Abstract
The agreement of Leaf Area Index (LAI) assessments from three indirect methods, i.e. the LAI–2200 Plant Canopy Analyzer, the SS1 SunScan Canopy Analysis System and Digital Hemispherical Photography (DHP) was evaluated for four canopy types, i.e. a short rotation coppice plantation (SRC) with poplar, a Scots pine stand, a Pedunculate oak stand and a maize field. In the SRC and in the maize field, the indirect measurements were compared with direct measurements (litter fall and harvesting). In the low LAI range (0 to 2) the discrepancies of the SS1 were partly explained by the inability to properly account for clumping and the uncertainty of the ellipsoidal leaf angle distribution parameter. The higher values for SS1 in the medium (2 to 6) to high (6 to 8) ranges might be explained by gap fraction saturation for LAI–2200 and DHP above certain values. Wood area index –understood as the woody light-blocking elements from the canopy with respect to diameter growth– accounted for overestimation by all indirect methods when compared to direct methods in the SRC. The inter-comparison of the three indirect methods in the four canopy types showed a general agreement for all methods in the medium LAI range (2 to 6). LAI–2200 and DHP revealed the best agreement among the indirect methods along the entire range of LAI (0 to 8) in all canopy types. SS1 showed some discrepancies with the LAI–2200 and DHP at low (0 to 2) and high ranges of LAI (6 to 8).

Keywords: LAI–2200; SunScan; DHP; indirect methods; direct methods; Wood Area Index

1. Introduction
Canopy leaf area is a crucial driver of light interception, and thus of photosynthetic carbon uptake and biomass production (GCOS 2011). Leaf area index (LAI), the metric of canopy leaf area, is commonly defined as half of the total leaf area per unit ground surface area (Chen & Black 1992). LAI is closely related to vegetation-atmosphere interactions as well as to gas exchange processes as photosynthesis and evapotranspiration (Duchemin et al. 2006). Being a key variable in ecological, hydrological and biogeochemical models and a reliable indicator of crop productivity, LAI is used to facilitate the understanding of dynamic vegetation changes and of the impact of climate change on ecosystems (Lin et al. 2016).

Unfortunately, the direct quantification of LAI requires a lot of manual labour as it implies the physical measurement of the area of leaves obtained from the destructive sampling of (parts of the) vegetation or by collecting leaf litter. The destructive sampling of evergreen, especially coniferous, species needs a very premeditated protocol. Morphological properties (e.g. specific leaf area) of needles differ along the vertical crown profile, among needles of different ages as well as among trees of different sizes due to competition pressure (Konôpka & Pajtík 2014). For tree genera that produce leaves at different time intervals during the growing season, as for example poplars, litter trap data represent an overestimation of the maximum LAI (Jonckheere et al. 2004). Destructive harvesting introduces a permanent disturbance to the canopy and is nearly impossible in forest canopies. It is furthermore not always possible to collect data along the entire season as the collection of leaf litter can only be used to estimate the seasonal LAI maximum and the pattern of LAI during leaf fall. It is therefore dif-

The Scots pine (*Pinus sylvestris* L.) stand is located in the urban mixed forest 'De Inslag' (150 ha) in Brasschaat, province of Antwerp. The selected stand is about 1.7 ha with an overstory of Scots pine and an understory of mosses, grasses (*Molinia caerulea* [L.] Moench), *Betula pendula* Roth and young Scots pine seedlings (Curiel Yuste et al. 2005). It was originally planted in 1929 and regularly thinned and managed since then. In 2011 the stock density was 360 trees ha⁻¹ while diameter at breast height and tree height were on average 33 cm and 21.4 m, respectively (Gielen et al. 2013). The stand canopy is sparse and according to assessments in 2007 the LAI was 1.31 m² m⁻² with only two needle age classes present (Op de Beeck et al. 2010). In August 2015 the stand was most recently thinned, reducing the number of trees with about one third (Gebauer et al. 2015). Both the SRC plantation and the Scots pine stand host eddy covariance monitoring stations that are part of the European ICOS infrastructure network (www.icos-etc.eu).

The Pedunculate oak (*Quercus robur* L.) stand is also located in the forest ‘De Inslag’, close to the Scots pine stand. The oaks were planted in 1936 with a current density of 310 trees ha⁻¹. The most recent assessments (2005) reported that canopy height was on average 26 m (Curiel Yuste et al. 2005). No thinnings were made in this stand.

The maize (*Zea mays* L.) field was located in Wilrijk, Antwerp. It was cultivated by a local dairy farmer for silage production. The maize crop (variety GL Fantas tic) was sown on 5 May 2015 after application of manure (60 m³ ha⁻¹) and ploughing the field to 25 cm depth. The date of seedling emergence was 20 May 2015. The planting design comprised an inter-row distance of 70 cm and an average distance between plants in the row of 14 cm. The sowing density was about 94,000 seeds ha⁻¹ with a SW-NE row direction.

### 2.2. Indirect optical methods

Three widely applied instruments for indirect LAI measurements were used in this study, *i.e.* the LAI–2200 Plant Canopy Analyzer (LI–COR®, Lincoln, NE, USA), the SS1 SunScan ceptometer (Delta–T Devices Ltd, Cambridge, UK) and Digital Hemispherical Photography (DHP). The theory of leaf area index calculation has been explained in detail in the Appendix text 1. Theory of leaf area index calculation.

#### 2.2.1 LAI–2200 Plant Canopy Analyzer

The LAI–2200 Plant Canopy Analyzer (LI–COR®, Lincoln, NE, USA), further referred to as LAI–2200, measures the canopy transmittance of diffuse light at five zenith angles, which is obtained from simultaneous measurements of diffuse light above and below the canopy with a fish-eye PAR sensor divided in five concentric rings. LAI is estimated by inverting the measured canopy transmittance (*Eq. 1 in Appendix text 1*) and taking into account the Apparent Clumping Factor (ACF) under the usual assumption that leaves are randomly (Poisson) distributed in the canopy (*cfr.* user manual of the LAI–2200 Plant Canopy Analyzer).

In this study the below-canopy measurements were manually taken with one LAI–2200 sensor, while above-canopy measurements were collected with another LAI–2200 sensor installed in a clearing close to the site. This sensor was set to automatically log incoming light readings at a 30 s interval during below-canopy measurements, which were afterwards matched to the closest readings in time. To avoid any influence from the operator the standard five ring configuration was used with a 45° view cap on both above- and below-canopy sensors. All LAI–2200 measurements were processed with the FV2200 software (v 1.0.0).

#### 2.2.2 SS1 SunScan Plant Canopy Analysis System

The SS1 SunScan Plant Canopy Analysis System (Delta-T Devices, Cambridge, UK), further referred to as SS1, is a ceptometer that uses measurements of radiation transmittance through the canopy to provide LAI estimates by applying the Beer-Lambert extinction law (*Eq. 3 in Appendix text 1*) and taking into account other parameters as absorption and transmission of diffuse light, and zenith angles (*cfr.* user manual of the SunScan Canopy Analysis System version 3.3). This method requires simultaneous measurements of both incident and transmitted photosynthetically active radiation (PAR), a requirement that was met in different ways depending on the canopy type. For the SRC, the Scots pine and the Pedunculate oak stands, two instruments were used that independently collected above- and below-canopy measurements, similar to the methodology explained above for the LAI–2200. In the maize crop only one instrument was used. This instrument was radio connected to an external PAR sensor measuring incoming PAR, allowing for simultaneous above- and below-canopy PAR readings.

The SS1 SunScan ceptometer uses a specific term to define the Ellipsoidal Leaf Angle Parameter (ELADP). This parameter is modified depending on the canopy and characterizes the horizontal or vertical orientation of the leaves (*cfr.* user manual of the SunScan Canopy Analysis System version 3.3). Because site-specific ELADP values were not available, ELADP was set to 1 for the SRC and the Scots pine and Pedunculate oak stands, and set to 1.37 for the maize crop. The SS1 does not account for clumping.
2.2.3 Digital Hemispherical Photography (DHP)

With this method, which is also known as fish-eye photography and further referred to as DHP, LAI is derived with the inverted Poisson model (Eq. 2 in Appendix text 1) from the amount and the distribution of vegetation pixels on digital hemispherical pictures of the canopy. In this study, the hemispherical pictures were first transformed into binary black and white pictures using the Ridler-Calvard thresholding algorithm (Ridler & Calvard 1978). Gap fraction was estimated and LAI was calculated by inversion of the Poisson model as described by Thimonier et al. (2010), and by accounting for clumping using the logarithmic averaging method (Lang & Xiang 1986). All the above calculations are implemented in the HemiTool software, which is the standard processing protocol for hemispherical imagery as a standard LAI measurement method at all ecosystem stations of the ICOS research infrastructure (www.icos-etc.eu).

All hemispherical pictures were taken with a digital single-lens reflex camera (DSLR; Nikon D7100, Tokyo, Japan) in combination with a hemispherical lens (4.5 mm F 1:2.8 DC HSM Sigma Corporation, New York, USA). Following the ICOS measurement protocol, pictures were made in RAW format, using the auto-focus of the lens, a fixed aperture of 8, and the lowest shutter speed at which no overexposure occurred. The minimum camera-to-foliage distance was 15 cm from the closest leaf or 10 times the leaf length.

2.3. Sampling design

All LAI measurements with the three indirect methods were collected over the span of one full growing season, from spring 2015 to spring 2016. Measurement dates were selected to collect data over the full environmental range of LAI values for each canopy type, including the seasonal minima and maxima. Due to some instrument failure and periods of unfavourable weather conditions, it was unfortunately not possible to measure with all three indirect methods at all scheduled dates. All indirect measurements were done under fully overcast sky conditions, i.e. in the absence of direct sunlight. In the SRC and the maize field, also direct LAI measurements were collected.

2.3.1 Short rotation coppice poplar plantation

Measurements in the SRC plantation were carried out in three permanent plots of 3 m by 4 m inside each of eight selected blocks, each block representing a different poplar genotype. At each measurement date 12 below-canopy readings were made in each plot with the LAI–2200 and SS1, six parallel and six perpendicular to the rows (Fig. 1a).

Above-canopy readings for both instruments were taken in a nearby clearing. In each of the 3 × 8 plots two hemispherical pictures were taken parallel to the rows with the camera positioned as close to the ground as possible (Fig. 1a). Measurements were taken about every two weeks between the time of bud break and the end of leaf fall, as well as one measurement during the leafless period in winter.

Fig. 1. Description of the sampling design in the different ecosystems. Measurements were performed in a short rotation coppice poplar plantation (a), in a maize field (b) and in a mature Scots pine and a mature Pedunculate oak stand (c). Location of the three indirect measurements (LAI–2200, SS1 and DHP) are reported in all ecosystems and litter trap positions in the short rotation coppice.
Direct LAI measurements in the SRC plantation were obtained with the gravimetric method (Daughtry 1990) from leaf litter collected at regular intervals from the start to the end of the leaf fall period, i.e. from late August to December 2015. In each plot, leaf litter was collected in three plastic litter traps (surface area of 0.22 m²) installed along a diagonal transect (Fig. 1a). Collected leaves were transported to the laboratory, dried in a drying oven at 70 °C until constant weight and then weighed. Total leaf area (LA) was calculated from dry weight using specific leaf area (SLA), which was determined from a representative sample of nine leaves collected from each plot at the time of maximum LAI (LAI\textsubscript{max}). SLA was calculated by dividing fresh leaf area of the sample by its dry weight. For each plot LAI was obtained by dividing the total LA by the total ground surface area of the three litter traps inside the plot (Broeckx et al. 2015).

2.3.3 Maize field

Indirect measurements in the maize field were taken in a 3 m by 3 m plot almost every two weeks. At each measurement date 49 below-canopy measurements were made with both LAI–2200 and SS1, one measurement spaced 5 m apart from the other, and with the sensor always pointing to the South. Simultaneous above-canopy measurements were taken in a nearby clearing. Nine upward-facing hemispherical pictures were taken at 1.3 m above the ground, the upside of the picture placed to the North, with 15 m distance between each picture taken. No direct measurements of LAI were collected in these two forest stands.

3. Results

This section shows the results of each statistical analysis, i.e. Passing & Bablok (P–B), Bland and Altman (B–A), Bravais-Pearson correlation coefficient (r) and scatter plots. For reasons of simplicity, the LAI ranges were arbitrarily divided in the following order: low (0 to 2 m² m⁻²), medium (2 to 6 m² m⁻²) and high (6 to 8 m² m⁻²) LAI range. The inter-comparison of the indirect methods (LAI–2200, SS1 and DHP) in the four canopies (SRC, Scots pine, Pedunculate oak and maize field) is first broken down (Fig. 2). Afterwards the comparison between the indirect and direct methods (litter fall and harvest) was performed for validation in SRC, and maize field only (Fig. 3).

3.1. Passing-Bablok regression results between indirect and direct methods

Focusing on the 95% CIs of the P-B regression terms for the comparison of indirect methods, the LAI–2200 and SS1 methods were the most comparable in the Pedunculate oak stand and the maize crop, as they provided similar LAI values based on the 95% CI of intercept and slope coefficients. The LAI–2200 and DHP methods agreed very well in the Scots pine stand and in the SRC. Compared with the direct method, LAI–2200 and DHP readings in the maize field provided unbiased LAI measurements (Table 2). For all other indirect methods there was either a constant bias (when the intercept differed significantly from 0), or a proportional bias (when the slope differed significantly from 1), or both biases were jointly detected (Fig. 2). These afore-mentioned results need, however, to be interpreted with care because the assumptions underlying the linear regression model were not always met.
Fig. 2. Inter-comparison of indirect methods for leaf area index (LAI) estimations. Panels on the left (a–c) show the conventional x–y scatter-plots with LAI readings. Panels on the right show the Bland and Altman (B–A) plots separately for each canopy type and for each pair of methods. The horizontal axis in the B–A plots represents the averages of each pair of measurements, while the vertical axis indicates the percentage differences (Δ) for each pair of measurements, explaining an overestimation or underestimation if the percentage is positive or negative, respectively. Red smoothed lines denote the systematic error (bias) and limits of agreement. SRC: short rotation coppice.
Fig. 3. Comparison of indirect vs. direct methods for leaf area index (LAI) estimations. Panels on the left (a–c) show the conventional x–y scatter-plots with LAI readings. Panels on the right show the Bland and Altman (B–A) plots separately for each canopy type and for each pair of methods. The horizontal axis in the B–A plots represents the averages of each pair of measurements, while the vertical axis indicates the percentage differences (Δ) for each pair of measurements, explaining an overestimation or underestimation if the percentage is positive or negative, respectively. Red smoothed lines denote the systematic error (bias) and limits of agreement. SRC: short rotation coppice.
Table 2. Results of the statistical analyses used for the inter-comparison between the three indirect methods and the comparison of the indirect with the direct methods (litter fall and harvest) in the four canopies studied (SRC, Scots pine, Pedunculate oak and maize field). The Bias column represents the constant (C) and proportional (P) systematic errors within their associated 95% confidence interval (CI) after judgement of the 0 and 1 values for the intercept and slope. N denotes the number of paired observations. Pearson’s correlation (r) and intercept and slope coefficients of the simple linear regression model were estimated through the Passing and Bablok (P–B) non-parametric procedure. Est, Low and Upp columns report the estimated, the lower and the upper 95% (CI), respectively, associated with intercept and slope. SRC: short rotation coppice.

n.a. indicates not available value occurring when the procedure failed to converge because of small sample size. r as well as the intercept and slope of the simple linear regression model were estimated according to the non-parametric P–B procedure.

3.2. X–Y scatter plot results between indirect and direct methods

The conventional x–y scatter plots for pairwise comparison of methods (left panels of both Figs. 2 and 3), showed some clear curvature. Among the indirect methods the best agreement was found between the LAI–2200 and DHP, as reflected by the data points close to the 1:1 line (Fig. 2b). The comparison of SS1 with the two other indirect methods yielded a more exponential curve, deviating from the 1:1 line (Fig. 2a and c). The comparison between the direct and the indirect methods showed a general overestimation in SRC and maize field canopies by all indirect methods, especially in the higher LAI range and in the SRC.

3.3. Bland and Altman results between indirect and direct methods per canopy type

The B–A analysis for the inter-comparison of the indirect methods is depicted separately for each canopy type (right panels of Fig. 2). The main results are reported for each canopy type in terms of bias and of Limits of Agreement (LoA). Note that for low LAI values, small absolute differences resulted in high relative variations (in %), and consequently the LoA diverged.

First, in the SRC, the LAI measurements obtained with DHP and LAI–2200 agreed best, especially in the high LAI range, characterized by a low bias and narrow LoA. In the low-to-medium LAI range, however, DHP produced higher values than LAI–2200; some source of bias as well as diverging LoA were observed. SS1 yielded slightly lower values than LAI–2200 and DHP in the low and medium LAI ranges (up to 4–5 m² m⁻²), but higher values in the high LAI range. Secondly, in the Pedunculate oak stand, a good level of agreement was observed between SS1 and LAI–2200 (low bias and relatively narrow LoA). Measurements with DHP in the low-to-medium LAI ranges were higher than the measurements obtained with SS1 and LAI–2200.

Thirdly, in the Scots pine stand, LAI–2200 and DHP were again in better agreement than compared to SS1, which produced lower values than the other two methods. Due to some instrument failure only few data were available for LAI–2200 in the low LAI range leading to a poor method comparability in the Pedunculate oak and in the Scots pine stands. Finally, in the maize field the three inter-comparisons showed the same tendency, i.e. that LoA diverged with decreasing LAI.

The B–A analysis was also performed for the comparison of the indirect and the direct methods in both the SRC and the maize field (Fig. 3, right panels). In the SRC all three indirect methods overestimated the direct method. The most biased indirect method was the SS1 method, showing a positive bias of 50% at low LAI values, which decreased to about 25% in the medium-to-high LAI range. On the contrary, LAI–2200 and DHP methods showed a decreasing bias when LAI increased. The bias in the indirect measurements corresponded to an average overestimation of the direct measurements with 0.5 to 2 m² m⁻².

In the maize field only few measurements were obtained with LAI–2200, showing a positive bias of more than 50% in the very low LAI range while for the medium LAI the LoA were closer to 0 as LAI increased. The DHP method only slightly overestimated the direct method (harvest), as shown by a small bias (Fig. 3c, right panel). On the other hand, SS1 underestimated the direct measurements by about 25% (Fig. 3b, right panel).
4. Discussion

Since direct measurements of LAI are destructive and labour-intensive, indirect methods to assess LAI offer an important alternative. All indirect methods are, however, affected by various factors, as the algorithms and approach used, radiation conditions and zenith angle at the time of measurements, canopy characteristics and clumping (Ryu et al. 2010a). In the current inter-comparison of three indirect methods to measure LAI the different outcome depended on the methods used and the canopy type studied.

4.1. Explaining the agreement and disagreement among canopy types

For all four canopy types, the DHP and LAI–2200 methods showed the best agreement, better than each of them compared with SS1. These findings are in line with a previous study (Fang et al. 2014), and may be explained by the similar approach for the clumping correction in both instruments. Differences between DHP and LAI–2200 in the low-to-medium range of LAI (similar to Homolová et al. 2007) may be explained by the gap fraction factor highly sensitive to canopy structure, by leaf distribution and leaf plasticity (Lopez-Lozano et al. 2007). This indicates that clumping at the shoot level might explain the differences between both instruments as documented for a mature Scots pine stand (Jonckheere et al. 2005).

A better agreement between all three indirect methods in the four canopy types was observed in the medium range of LAI. There was a discrepancy between SS1 and the two other indirect methods in both the low (underestimation) and high (overestimation) LAI ranges. The lower values obtained with the SS1 method in the low LAI range, can be explained by the fact that this method did not account for clumping, thus underestimating results (Jones 2014). Clumping factors calculated with the DHP and LAI–2200 methods varied between 0.85 and 0.96 depending on the canopy studied and the method used. These results were in agreement with a previous validation (Ryu et al. 2010a). The lack of a clumping correction in the SS1 method could, thus, only partly account for the observed differences. The higher values obtained with the SS1 method in the medium to high range were possibly related to the levelling-off effect at LAI 5-6 m² m⁻² in the LAI–2200 and DHP methods, caused by the gap fraction saturation (Gower et al. 1999; Leblanc et al. 2005).

Finally, the discrepancy between the SS1 and the other indirect methods might also be due to the fact that the leaf angle distribution was a priori fixed in the SS1 method while it was calculated for each picture (DHP method) or for each set of measurements (LAI–2200 method).

4.2. Explaining the agreement and disagreement between indirect and direct methods

In the comparison of the indirect methods with the direct methods, the former overestimated the latter, with exception of SS1 in maize that showed an underestimation in the low-medium range of LAI. There was a clear difference between the two canopies tested, i.e. SRC and maize field. An exponential overestimation was found at the SRC (Fig. 3, right panels), which could be explained: (i) by the WAI in the SRC, and (ii) by the difference in the direct methods used. In the SRC the direct LAI was calculated from litter fall while in the maize field it was calculated from direct harvesting of all plant parts. In addition, the seasonal increment of the WAI in the SRC could explain the increasing difference between the indirect and direct methods. A previous study at the same site showed that the branch area increased with 0.60 m² m⁻² over three years (Broeckx et al. 2005). The systematic bias (of 25%) for the medium and high LAI values was in line with a previous report that woody material comprises 5% to 35% of the total PAI in forests (Gower et al. 1999).

The slight overestimations of the DHP method compared to the direct measurements in the maize crop agreed very well with earlier findings (Facchi et al. 2010) and might be explained by the presence of the large maize leaves. The underestimation of SS1 in maize was also observed in previous studies (e.g. Wilhelm et al. 2000) and was probably due to the lack of a clumping correction which explained the poor performance of SS1 at low LAI values and in row crops (Chiroro et al. 2006). The chosen ELADP for this canopy type may play an important role, and as the maize leaves change considerably along the growing season, the ELADP value may not have been accurate throughout the entire season (Fang, 2005).

5. Conclusions

Although indirect methods to estimate LAI have already been compared in previous studies, large uncertainties still remain. In the current study a standardized approach compared different indirect methods under contrasting canopies, and the results were validated with direct methods using more than one statistical analysis. The use of multiple instruments revealed, on the one hand, a considerable variability and thus, uncertainty in the measurements. On the other hand the approach helped to understand the factors determining LAI, such as the WAI and the degree of clumping, and how these factors differed among methods and canopies. It is, therefore, important to use more than one indirect method for measuring LAI. One suggestion for further research is that an improved hemispherical method is developed to indirectly measure LAI, which is able to simultaneously measure at different heights, providing information about clumping and leaf angle distribution. This improved method should
furthermore able to differentiate between non-green and woody parts of the canopy, by infrared techniques, as has been proposed (Jonckheere et al. 2004; Schaefer et al. 2015). For large-scale research infrastructures (as ICOS, LTER, IPCC-Forests) a harmonized or standard protocol should enable LAI measurements that can be compared among canopy types, sites and temporal scales.

Appendix text 1. Theory of leaf area index calculation

In-situ indirect measurements of LAI with optical instruments are based on a statistical and probabilistic approach of the distribution and arrangement of foliar elements (or their complement, the gap fraction) in the canopy. Two theoretical approaches have been developed to infer LAI from optical measurements. With the first approach, LAI is estimated by inversion of the exponential expression of the gap fraction (Eq. 1), i.e. by solving the expression for $L$ (Eq. 2):

$$P(\theta) = e^{G(\theta, \alpha) \Omega(\theta) \cos \theta}$$  \hspace{1cm} [1]$$

$$L = -(\ln P(\theta) \cos \theta)/G(\theta) \Omega(\theta)$$  \hspace{1cm} [2]$$

where $P(\theta)$ is the gap fraction, $L$ is the LAI, $\theta$ is the zenith angle of view, $\alpha$ is the leaf angle, $G(\theta, \alpha)$ corresponds to the fraction of foliage projected on the plane normal to the zenith direction, and $\Omega(\theta)$ is the clumping coefficient, which corrects for a deviation from the assumption of random (Poisson) distribution of canopy elements. When the foliage is randomly distributed within the canopy, $\Omega(\theta) = 1$, but as the foliage becomes more clumped, $\Omega(\theta) < 1$. The function $G(\theta, \alpha)$ depends on leaf angle distribution, which is generally not known a priori. The calculation of LAI therefore requires gap fraction measurements for a range of zenith angles of view.

The second approach is based on the Beer-Lambert extinction law expanded to plant canopies. This law expresses the attenuation of radiation in a homogeneous turbid medium. In such a medium the flux is proportionally absorbed to the optical distance. Assuming a random (Poisson) distribution of leaves within the canopy:

$$I = I_0 e^{kL}$$  \hspace{1cm} [3]$$

where $I$ is the incident radiation above the canopy, $I_0$ is the radiation transmitted below the canopy, and $k$ is the extinction coefficient, which depends on the leaf angle distribution and on the direction of the beam (e.g. $k = 1$ for entirely horizontal leaves). $I/I_0$ is theoretically equivalent to the gap fraction in Eq. 1, i.e. $P(\theta)$.

Whichever approach used, when applied to canopies with a significant woody-to-total plant area ratio, $L$ represents an overestimation of LAI because of the presence of light-blocking non-leaf and non-green elements. Consequently, $L$ provides an estimation of PAI rather than of LAI. To obtain LAI, a woody element correction factor has been introduced (Chen 1997):

$$LAI = L (1 - \alpha)$$  \hspace{1cm} [4]$$

where $0 \leq \alpha \leq 1$ is the proportion of woody-to-total plant area. Formally $\alpha = WAI/PAI$ where WAI is the wood area index, which can be estimated from destructive sampling by calculating the sum of the hemi-surface area of all branches and stems or taken from the literature, if available.

Appendix text 2. Statistical analyses

The Passing & Bablok (1983) regression is based on a robust, non-parametric model and is, unlike the Ordinary Least Squares (OLS) regression, not sensitive towards outliers. It assumes that measurement errors of both methods (direct and indirect) have the same distribution. The 95% confidence intervals (CI) of the intercept and slope terms of the Passing and Bablok regression equation $y = a + bx$ were interpreted to reveal a constant or a proportional bias. If the 95% CI for the intercept included the zero value, it could be concluded that there was no significant constant bias. If the 95% CI for the slope included 1 as a value, it could be concluded that there was no significant proportional bias. When both conditions were met, one could assume that $y = x$ and that there was no statistically significant difference between the two compared methods. In this latter case the two compared methods could be used interchangeably. In the present study the Passing and Bablok regressions were estimated through the PBreg function of the R MethComp package (Cartensen 2010).

The Bravais-Pearson correlation coefficient ($r$), which measures the strength of the linear relationship and which was calculated per canopy type, helped the understanding of the previous analysis. This method had to be carefully interpreted as the high r value was not a sufficient condition to affirm that two methods were in agreement; it simply showed the presence of a strong linear relationship between the two methods.

The Bland & Altman (1986) approach involves a graphical method (hereafter denoted as the B–A plot) consisting of a scatter plot where the difference between each pair of measurements is plotted against the average of each pair of measurements. The mean of the differences is shown on the plot as a reference line indicative of the systematic error (or bias). The 95% limits of agreement (LoA), which are calculated as the mean of the differences ±1.96 standard deviation (SD) of the differences, quantify the range of variability (i.e. precision) between the two measurements. LoA can be evaluated or compared with pre-determined limits to enable the researcher to decide whether given techniques have an acceptable agreement or repeatability. Therefore, assuming a negligible bias, the smaller the LoA, the better the agreement is. In this study an approach based on regressing the relative (%) differences to the averages was used, and the resulting equation was used to evaluate both the bias and the LoA. The relation between the relative LAI differences and the averages of the differences was estimated through a locally weighted scatterplot smoothing (LOWESS, Cleveland 1979). This is a non-parametric method, which combines much of the simplicity of linear least squares regression with the flexibility of non-linear regression. Fitting is done locally, i.e. at each point x in
the range of the data set a low-degree polynomial is fitted to a subset of the data using points in a neighbourhood of \( x \), weighted by their distance from \( x \). The LOWESS curve was computed through the \textit{loess.sd} function implemented in the \textit{msir R} package (Scrucca 2011).

Analysis of natural-production conditions for timber harvesting in European North of Russia

Ilya Shegelman¹, Pavel Budnik¹, *, Vyacheslav Baklagin², Oleg Galaktionov¹, Ivan Khyunninen¹, Artem Popov¹

¹ Petrozavodsk State University, Lenin Str., 33, 185910, Petrozavodsk, Russia
² Northern Water Problems Institute of the Karelian Research Centre of the Russian Academy of Sciences, Aleksander Nevsky Str., 50, 185030, Petrozavodsk, Russia

Abstract
Natural-production conditions determine operational efficiency of logging machines. This influence needs to be taken into account at different levels of forest management. It is necessary to allocate areas with similar natural-production conditions for effective forest management. It allows simplifying the decision making process for selecting logging technology and machines. The purpose of this study was to establish areas with similar natural and production conditions in the European North of Russia (ENR). In addition, for small enterprises, we recommend logging technologies and logging machines that can be used in established areas. We determined the indicators of the natural-production conditions of ENR regions and compared them. Cluster analysis was used to compare the indicators. We found that ENR can be divided into three main zones A, B, C and two subzones B1 and B2 with similar natural-production conditions. In the zones A, B and the subzones B1 and B2, small logging enterprises should use a harvester and a forwarder. In the zone C, the enterprises can use a logging system including a harvester and a forwarder or a logging system including a feller buncher, a skidder and a processor. The logging system should be based on the light class of logging machines for the zone A, the medium class or the heavy class for the zones B, C and the subzones B1, B2, the heavy class of machines for the zone C.

Key words: natural-production conditions; tree size; relief; soil conditions; timber volume; forest species composition, logging machines, cluster analysis

1. Introduction
Natural and production conditions determine operational efficiency of logging machines (Häggström et al. 2016; Alam et al. 2014; Nurminen et al. 2006). This influence needs to be taken into account at different levels of forest management: operational, tactical and strategic.

In order to assess the influence of natural-production conditions it is necessary to define the factors of such impact. It can be performed based on analysis of studies regarding the impact of natural-production conditions on operational efficiency of logging machines.

The influence of timber volume per hectare (ha), sizes of trees on the efficiency of harvester has been studied rather thoroughly (Kormanek et al. 2018; Laitila et al. 2013; Jiroušek et al. 2007; Ovaskainen et al. 2005; Kärhä et al. 2004; Eliasson 1998; Glöde 1999). These studies indicate that harvester efficiency increases with the increase of tree size. However such increase is not endless. For certain models of machines there are specific tree sizes the increase of which leads not to efficiency improving, but – on the contrary – to its loss (McNeel & Rutherford 1994; Kärhä et al. 2004).

Numerous research works reveal that there is a growth of diesel fuel consumption with the increase of sizes of treated trees and their species (Kellogg et al. 1994; Ackerman et al. 2017).

Large-size tree trunks can be a severe restriction to logging with the use of logging machines. For example, large trees and small timber volume per ha is a serious problem for using harvesting machines in rainforests (Castro et al. 2016).

The influence of timber volume per ha and sizes of trees on the operation of forwarders has been extensively studied (Kellogg & Bettinger 1994; Tufts & Brinker 1993). The studies show that the efficiency of forwarders increases with the increase of timber volume per ha and sizes of trees.

When it comes to the efficiency of timber harvesting, soil conditions are often determinant (Proto et al. 2018; Rozitis et al. 2017). The speed of skidding machines depends on the quality of skidding road surface. When skidding or transporting wood on soils with low bearing capacity, a track appears fast thus increasing resistance to motion. It leads to decline in productivity, fuel consumption increase and growth of the load on transmission.

A lot of works give evidence of negative impact of logging machines on soil during the process of timber harvesting (Klaes 2016; Reza et al. 2009; Schack-Kirchner et al. 2007). The negative impact is expressed in tracking and soil panning, preventing further timber regeneration. Waterlogged soils are especially vulnerable to such harm.

Relief of the terrain markedly affects the efficiency of logging machines and imposes restrictions upon their use (Strandgard et al. 2017; Tiernan et al. 2004). For instance, excavator-based harvesters are uncommonly used in Finland and Russian north despite their advantages over harvesters with specialized chassis (Palander et al. 2012, Bergroth et al. 2006; Wang et al. 2002). This is mainly due to restrictions on the use of such machines, even on small slopes.

Species of wood have structure and development specifics that substantially influence operational efficiency of logging machines. Therefore, species composition of stands shall be considered when analyzing natural-production conditions. Besides, species composition determines economic value of a forest stand. Economic value of woods depends on a wide range of factors: structure of stand, age, conditions of habitat and others. In the European part of Russia coniferous forests are more valuable and spreading than deciduous. Economic value of forest stand defines a forest entrepreneur’s possibilities to use more progressive machinery with the highest efficiency relating to performance and environmental safety at the expense of generated profits.

Peculiarities of species structure mostly influence operational efficiency of logging machines performing the following operations: felling, limbing, length bucking. Species’ influence on operational efficiency of logging machines has been studied not so extensively as other earlier mentioned factors of natural-production conditions (Petersons 2014). In general, many specialists have acknowledged that operation of logging machines is more productive and less problematic in coniferous forest stands than in deciduous forest stands.

Taking into account the influence of natural and production conditions of logging requires a high level of forest management. This implies the ability to analyze a large amount of information and make management decisions based on the analysis. In addition, a high degree of awareness of natural and production conditions of the forest resource base of the enterprise is required. Therewith it requires a wide fleet of logging machines, which gives the possibility to choose the most suitable logging machines for the specific area of the forest resource base.

This approach in forest management can be implemented in large enterprises. Small enterprises cannot take this approach. As a rule, they are contractors and their fleet includes one or two complexes. There is limited information on studies in substantiation of logging technology and logging machines for such enterprises. In Russia, the problem is complicated by the fact that small enterprises have to work in forest areas that are located in different subjects of the Russian region, and sometimes even in neighboring subjects of Russia. Thus, taking into account the size of the subjects of the Russia, enterprises operate in various natural and production conditions but are forced to use a limited fleet of logging machines.

We suppose that for small enterprises logging technology and logging machines should be universal and provide an opportunity to work in forest areas with a wide variety of natural and production conditions. However, at the same time, it is necessary to ensure that the technical characteristics of the logging machines are not excessive. For example, the use of logging machine in a small forest, which is designed to work in a large forest.

This approach can be implemented by solving the following tasks. First, territories with similar natural and production conditions should be allocated. At the same time, the allocated territories should be comparable in scale with forest areas, which the enterprises work. It allows simplifying the decision making process for selecting logging technology and machines. Secondly, the development of general recommendations on the applied logging technologies and logging machines for the allocated territories.

At the same time, we suppose that an objective approach to solving these problems can be the use of weighted average values that characterize the natural and production conditions of the allocated territories and variance of the values. This approach allows ensuring the universality of the selected technologies and logging equipment, as well as the use of logging machines with non-excessive technical characteristics.

The latest definition of territories with similar natural-production conditions in Russia was carried out in the eighties of the last century (Vinogorov 1986). The study was performed on the scale of the Soviet Union. Sizes of trees in forest stand and relief were the main indicators of natural-production conditions. However, the above research shows that it is necessary to take into account a greater number of natural-production conditions indicators. A number of other factors shall be also taken into account: soil conditions, timber volume per hectare, species composition of stands, location of merchantable forest and its accessibility. Besides, Vinogorov’s work (1986) does not consider specific features of certain regions.

The purpose of this study was to establish areas with similar natural and production conditions in the European North of Russia (ENR). In addition, the aim of the study was to develop recommendations for the use of logging technologies and logging machines for the established areas.
2. Materials and methods

2.1. Study outline and methods

The research includes the following steps: 1) collecting data for defining natural-production conditions indicators of ENR; 2) comparing the indicators and identifying zones with similar natural-production conditions; 3) confronting technical characteristics of logging machines with natural-production conditions and development of recommendations for using logging machines in the identified zones.

The step 2 contained three sub-steps. We calculated the values of the indicators at the first sub-step. At the second sub-step, we combined indicators into sets describing various aspects of natural-production conditions. At the third sub-step, we compared the sets and based on this identified zones with similar natural-production conditions. Tree clustering analysis was applied in the third sub-step. We employed single linkage for the linkage rules and Euclidean distances (ED). Tree clustering analysis was performed using STATISTICA on a PC.

The step 3 contained four sub-steps. We collected data on the technical characteristics of logging machines and data on their application at the first sub-step. At the second sub-step, we determined the feasibility of using models of logging machines in conditions of the identified zones. At the third sub-step, we divided logging machines into classes depending on its technical characteristics. At the last sub-step, we have developed recommendations for using the models of logging machines in the identified zones.

Method of expert evaluation was used in the step 3. The method had two stages. At the first stage, we determined the possibility of using the models of logging machines in the conditions of identified zones. To do this, we compared the technical characteristics of logging machines models and the natural-production conditions of zones. We took into account the recommendations of the manufacturer of the models of logging machines and information about their application. At the second stage, experts were involved. The experts were logging foremen and operators of logging machines. Each expert was invited to evaluate and comment on the results obtained in the first stage. The results were then analyzed and summarized.

2.2. Study region

Study region is European North of Russia (Fig. 1). ENR includes: Murmansk Region, the Republic of Karelia, Arkhangelsk Region, Vologda Region, Komi Republic, and Nenets Autonomous Area. More than 40% of forest resources of Russian European part are concentrated on the territory of ENR, and forest and woodworking industries are among the main ones in the economic structure.

This study has not considered Nenets Autonomous Area. The reason for this is that timber resources of 18.2 mln. m³ are negligible in comparison with the other regions included into ENR. Besides Nenets Autonomous Area scarcely carries our works on timber harvesting. As reported by the Federal Forestry Agency felling volume in 2017 will be only 1.9 thous. m³.

Fig. 2 shows comparative diagrams of timber resources and the intensity of timber harvesting in ENR regions.

More than half of timber resources in ENR are situated in Komi Republic – 3 114 mln. m³ and Arkhangelsk Region – 2 688 mln. m³ (Fig. 2A). However, in the context of timber harvesting and applied machines, it is reasonable to assess timber resources in mature and old growth forests, situated on the territory of merchantable forests. According to the RF legislation industrial harvesting are conducted in merchantable forests. In total timber resources of Komi Republic 65% fall to the share of mature and old growth forests in merchantable forests. In other ENR regions this share is less than 50%: Arkhangelsk Region – 46%, Vologda Region – 48%. In the Republic of Karelia only 29% fall to the share of mature and old growth forests in merchantable forests.

Utilization rate of timber resources can be evaluated based on felling volume and annual allowable cut use. Annual allowable cut is a scientifically grounded volume of sustainable yield.

According to the Federal Forestry Agency the largest wood volume in 2017 was harvested by Vologda and Arkhangelsk Regions – 15.6 mln. m³ and 12.7 mln. m³, respectively (Fig. 2B). Despite the greatest timber resources in mature and old growth forests in merchantable forests among other ENR regions, Komi Republic takes the third place in felling volume – 8.7 mln. m³. It is basically explained by lower intensity of timber harvesting in the republic. Thus, when the share of annual allowable cut development in Arkhangelsk Region, Vologda Region and the Republic of Karelia is more than 50%, it is only 27% in Komi Republic (Fig. 2C). The Republic of Karelia has the highest percentage of annual allowable cut development – 64%.
2.3. Indicators of natural-production conditions

We propose to compare natural-production conditions of ENR regions by comparing a number of indicators. Table 1 shows the list of indicators and their values for ENR regions. Table 2 shows sources of indicators data.

Average volume of stem (indicator 4) has been calculated based on forest taxation data of the forest areas included into the respective ENR regions according to the expression:

\[ q_{av} = \sum_{i=1}^{n} \frac{Q_i}{n} \cdot q_{av} \]

where \( q_{av} \) – average volume of stem in the region, \( Q_i \) – timber resources in merchantable forest for the \( i \)-th forest area of the certain ENR region, \( q_{av} \) – average volume of stem for the \( i \)-th forest area, \( n \) – total number of forest areas in the region.

Maximum volume of stem (indicator 5) is the largest value of \( q_{av} \). Minimum volume of stem (indicator 6) is lowest value of \( q_{av} \).

Mean height of forest stands (indicator 7) has been defined as per appraising scale applied in the RF, where, average site quality of forest and the determined felling age as per dominant coniferous species have been the input information. For this purpose data on the classification of stands in merchantable forests by site qualities and information about planned felling age have been collected and analyzed.

The indicators 12–15 shows ratios of soil conditions classes. Class 1 includes dry sands and stony soils. Under class 1 works on felling area can be performed throughout the year almost without restrictions. Class 2 includes sandy-loam soils and fine loam soils. The decrease of bearing capacity of soils due to the decrease of bearing capacity of soils. Class 3 includes clayed soils, sand loams with clay courses. Such soils have high contents of moisture during whole warm season. Working under such conditions machines ruin surface soil fast and form track pits. Class 4 includes peat-bog and humus gley soils. They become impassable during the periods of steady rains, and have low bearing capacity during dry season.

Timber volume per ha (indicator 16) for ENR regions has been determined according to the expression:

\[ SV = \frac{\sum_{i=1}^{n} Q_i}{\sum_{i=1}^{n} S_i} \]  

where \( SV \) – average timber volume per ha, \( S_i \) – area of the \( i \)-th forest area.

Indicator 17 is lowest value of timber volume per ha for \( i \)-th forest areas in the region. Indicator 18 is largest value of timber volume per ha for \( i \)-th forest areas in the region.

We conducted an analysis of the natural-production conditions by comparing sets of indicators. The description of the sets is given in Table 3.

2.4. Classification of timber harvesting machines

Two systems of logging machines are most common in Russia (Goltsev at al., 2011). The first system (HF) includes a harvester and a forwarder. The second system (FSP) includes a feller buncher, a skidder and a processor. Two types of skidders are used in Russia: with arch grapple and clam bunk skidders. Excavator-based harvesters are often used as processors. We separate three classes of logging machines: light (L), medium (M) and heavy (H). The technical characteristics of the classes are given in Table 4.

Logging machines on a wheeled chassis and on tracked chassis are used on forest harvesting. Logging machines on a wheeled chassis have 4×4, 6×6 and 8×8 axle configuration and can have antiskid chains. Some forest machines used in Russia have complicated cab levelling systems and system of self-propelled chassis active stabilization.
3. Results

3.1. Assessment of the similarity of natural-production conditions

Comparison of NPS sets (name set, see table 3) showed that the natural-production conditions of the Republic of Karelia are the closest to the natural-production conditions of Arkhangelsk region (ED 3.63). The most different are the natural-production conditions of Murmansk region and Vologda region (ED 9.91). The natural-production conditions of Komi Republic are closest to Arkhangelsk region (ED 4.96) and to the Republic of Karelia (ED 5.41). The natural-production conditions of Murmansk region and Vologda region are the most different from the natural-production conditions of other ENR regions. ED are in the range 6.45–9.91 for Murmansk Region and 5.94–9.91 for Vologda Region. Fig. 3 gives dendrogram of Euclidean distances between five studied regions calculated using cluster analysis based on NPS sets describing various aspects of natural-production conditions.

Comparison of ATD sets showed that the average taxation data of forest stands of Murmansk region and the Republic of Karelia are the most similar (ED 1.98). The average taxation data Arkhangelsk region are most similar to the average taxation data of the Republic of Komi (ED 4.96). The average taxation data of Vologda region is the most different from the average taxation data of other regions in particular Murmansk region (Fig. 4).

Fig. 5. Dendrogram of Euclidean distances between five studied regions calculated using cluster analysis based on TMed sets describing various aspects of natural-production conditions.

The sizes of maximum tree and medium tree are close in The Republic of Karelia and in Komi Republic (ED 0.63 and 0.65 respectively). From all ENR regions, sizes of trees are close in three regions (the Republic of Karelia, Komi Republic and Arkhangelsk Region). ED are in the range 0.6–1.07 for TMed sets and 0.63–1.79 for TMax sets. The sizes of maximum trees and medium trees in Vologda Region and in Murmansk Region are the most different from maximum and medium sizes of trees in other ENR regions. ED are in the range 1.9–3.91 for Murmansk Region and 2.02–3.91 for Vologda Region. Murmansk Region and Vologda Region differ most by these sets (ED 3.91).

Fig. 6. Dendrogram of Euclidean distances between five studied regions calculated using cluster analysis based on TMax sets describing various aspects of natural-production conditions.

Fig. 7 gives the results of CLC sets comparing. The soil conditions and the land form conditions are most similar in Arkhangelsk Region and Vologda Region (ED 0.67). The Republic of Karelia is approaching these regions by these conditions. The soil conditions and the land form conditions of Murmansk Region and Komi Republic are vary most considerably from other ENR regions. ED for Murmansk Region are greater than 3.9. ED for Komi Republic are greater than 3.3.

Fig. 7. Dendrogram of Euclidean distances between five studied regions calculated using cluster analysis based on CLC sets describing various aspects of natural-production conditions.

Fig. 8 gives the result of SC sets comparison. The forests of Murmansk region are similar to the forests of the Republic of Karelia by their species composition (ED 0.41). The forests of Arkhangelsk Region are similar to the forests of Komi Republic by their species composition (ED 2.01). The species composition of forests in Vologda region is very different from other ENR regions (ED > 3.6). The forests of Vologda region are most significantly different from the forests of Murmansk region in terms of species composition (ED 4.05).

Fig. 8. Dendrogram of Euclidean distances between five studied regions calculated using cluster analysis based on SC sets describing various aspects of natural-production conditions.

Based on the results of cluster analysis in ENR, three zones of natural-production conditions can be identified (Fig. 9). Zone A includes Murmansk region. Zone B includes the Republic of Karelia, Komi Republic and Arkhangelsk Region. Zone C includes Vologda Region. Analysis of soil conditions and land form conditions and 9–15 indicators showed that it is advisable to allocate subzones B1 and B2. These subzones take into account the presence of undulating topography unusual for zone B. Zone B1 includes West Karelian upland. Zone B2 includes Northern Urals, Subpolar Urals, Polar Urals.
3.2. Comparison of technical characteristics of logging machines and natural-production conditions

The comparison of natural-production conditions and technical characteristics of logging machines allowed to make recommendations on the systems of logging machines that can be used in ENR regions. Table 5 summarizes the results of the comparison.

HF system is most applicable in all ENR regions for small logging enterprises. However, for zone A, HF system should be formed from L class of logging machines, for zone B from M or H class, for zone C from H class. FSP system can be used in Vologda Region, especially in its southern part.

Soil conditions of classes 3 and 4 predominate in ENR regions, except for Murmansk Region. High bogginess is typical for Komi Republic, The Republic of Karelia, Arkhangelsk and Vologda Regions. Therefore, in B and C zones (except for B1 and B2 subzones) it is necessary to use either logging machines on a tracked chassis or on a wheeled chassis with tracks for wheels and 6×6 or 8×8 axle configuration. In B1 and B2 subzones, the feasibility of using wheeled chassis with 6×6 or 8×8 axle configuration is explained by the need to ensure stability on slopes. Logging machines with 6x6 or 8x8 axle configuration have better stability. The use of tracks for wheels is explained by a decrease in the negative impact on the soil. Tracks for wheels are used to ensure passableness of logging machines in B and C zones.

Logging machines may be not equipped with cab leveling system and system of self-propelled chassis active stabilization in Vologda Region and Arkhangelsk Region and The Republic of Karelia (zones B and C except for B1 and B2 subzones) because relief on the forest areas of these regions is mainly characterized by slopes with less than 15° slope ratios. Areas of forest stands in zone A and subzones B1 and B2 (Murmansk Region and the part of Komi Republic and the part of The Republic of Karelia) are defined by the most rugged topography. Almost all the territory of Murmansk Region has an undulating land. In this region, logging machines must be equipped with cab leveling systems and system of self-propelled chassis active stabilization. Such systems should be equipped with machines used in the Western part of the Republic of Karelia (zone B1) and the Eastern part of Komi Republic (zone B2).

Fig. 9. Zones of natural-production conditions in ENR.
4. Discussion

Our results indicated high variability of natural-production conditions in the ENR regions. Except for Murmansk Region, ENR regions are similar in soil conditions and land form conditions. Species composition varies in ENR regions, however prevailing species are analogous. Sizes of trees in forest stands are the most considerable difference between ENR regions. Actually ENR regions can be divided into three groups by sizes of trees in forest stands. Murmansk Region refers to the first group which is characterized by the smallest sizes of trees. The second group described by middle-sized trees includes the Republic of Karelia, Komi Republic and Arkhangelsk Region. Vologda Region refers to the third group defined by the largest trees in forest stands.

The study evidence that in ENR there are several zones with the same natural-production conditions. The zones have special aspects that must be considered when choosing logging machines. Currently, the logger is trying to purchase heavy logging machines but the results indicate that all classes of logging machines can be used in ENR. Thus, the logging approach can be more flexible even for small enterprises.

In addition, the study showed that for small enterprises it is advisable to use HF system. This system is more universal for ENR than FSP system in ENR. As disadvantages of FSP system for ENR, experts noted machinery downtime associated with expectation of relocation. The sizes of cutting areas in ENR are small (10–15 hectares). FSP system has high productive so it processes the cutting area quickly. There is a need for frequent relocations. FSP system consists of three logging machines as against HF system that has two machines. The problem is complicated by the fact that in the most part of ENR has a low road density (indicator 24), and a relatively small hectare timber volume per ha (indicator 24). This leads to an increase in the relative cost of logging and machinery downtime. In general, FSP system requires a higher level of planning of logging operations under natural-production conditions of ENR. FSP system is advisable to use in Vologda region, where the forest is larger and higher level of road density. Disadvantages of FSP system for ENR are impossibility of strengthening skidding road with wood residues and contamination of wood while skidding.

These results are consistent with the results of Syunev et al. (2009), Goltsev et al. (2011) who presented a comparative appraisal of using logging system in Northwest of Russia.

For zones B and C, we do not recommend using logging machines with cab leveling system and system of self-propelled chassis active stabilization. This is because logging machines equipped with the systems tend to be more expensive than machines without such the systems and relief has relatively mild slopes (up to 15°) in the zones. Under such approach ergonomic working conditions of a logging machine operator deteriorate, but at the same time machine price and service charge will be considerably lower what is mostly important for small enterprises.

In our study, we used 46-year old data on diameter distribution given in Vinogorov (1972). The data were obtained from the measurement of 4.8 million trees. Conducting such a number of measurements is currently difficult. It is known from forest estimation that diameter distribution is subject to certain objective laws (Tyabera 1980; Picard et al. 2016). Conditions of habitat, species composition, age, density of stand, configuration of stand, economic activity in forest, environmental drivers, natural catastrophes, in particular fires, hurricanes, are the factors influencing diameter distribution in forest stand. Diameter distribution changes over time (Vacek et al. 2018).

According to Russian legislation, logging can only be carried out in forests that have reached a certain age. This age has not changed since the time of Vinogorov’s research. Thus, we consider forests of the same age. We compared the data on the average volume of stem and the average timber volume per ha corresponding to the time of Vinogorov’s research, with modern data. The data does not differ. Therefore, we consider it possible to use the Vinogorov’s data for the present-day planning.

All conclusions are based on analysis, the available data and own sample observations. There are reasons that may limit the significance of the research results. First, it is reliability of the data used in the study. Secondly, it is limited number of the indicators used in the study that characterize natural and production conditions. In addition, the opinion of experts, whose objectivity is limited, was used in the development of recommendations on logging machines.

Small enterprises can use the results of the study in the planning of logging operations. In addition, the method of allocation of territories with similar natural-production conditions based on cluster analysis can be used by logging enterprises in the analysis of their own allocated timber supply area. Besides the researches findings are currently important for a buyer of logging machine allowing to make a well grounded choice of certain model among the whole variety of designs, and for a seller allowing to assess the characteristics of his models in the context of forest exploitation conditions of certain regions and make a commercial proposal based on the results of such assessment.

5. Conclusion

In consequence of the conducted study, it has been established that natural-production conditions in ENR regions are similar in relief and soil conditions. ENR regions vary most considerably in sizes of trees in forest stands and timber volume per ha. From the results,
ENR can be divided into three main zones A, B, C and two subzones B1 and B2 with similar natural-production conditions. In the zones A, B and the subzones B1 and B2, small logging enterprises should use a harvester and a forwarder. In the zone C, the enterprises can use a logging system including a harvester and a forwarder or a logging system including a feller buncher, a skidder and a processor. The logging system should be based on the light class of logging machines for the zone A, the medium class or the heavy class for the zones B, C and the subzones B1, B2, the heavy class of machines for the zone C.

Acknowledgments

The researches have been performed within the frameworks of implementing grant of the President of the Russian Federation No MK-5321.2018.8.

**Abstract**

Long-term temporal development of beech stands in relation to climatic conditions is well documented by dendrochronological analyses. The study aims to identify and describe growth factors affecting natural European beech stands (*Fagus sylvatica* L.) on permanent research plots in the eastern Krkonoše Mountains, the Czech Republic. The paper focuses on radial growth dynamics, frequency and cyclicity, and the effect of climatic factors on diameter increment of beech stands since 1850. The growth development of beech stands was significantly affected by air pollution load in 1977–1989, and increasingly frequent climate extremes in recent years (since 2010). Periodic increment events recurred in approximately 10–18 years’ periods. Stands on research plots responded differently to climatic factors, the main limiting factor being low temperatures during the growing season, frost damages and extreme droughts. The positive influence of temperatures on beech increments was recorded in winter, early spring, and especially in July and August of the current year. Conversely, precipitation in the previous year had higher impact on radial increment, with prevailing negative correlation. The plots were negatively affected by the decrease in sum of precipitation in February and March, but it was the temperature that influenced the beech increment most significantly. Dendrochronological analysis of close-to-nature beech stands provides valuable information on radial forest growth in response to changing climatic conditions.

**1. Introduction**

In terms of ongoing global climate change, European beech stands (*Fagus sylvatica* L.) show greater stability and resistance to water scarcity than Norway spruce stands (*Picea abies* [L.] Karst.) – (Dittmar et al. 2003; Zang et al. 2011, 2014; Hartl-Meier et al. 2018). Climate change has long been forcing forestry management to change its approach to tree species composition in favour of deciduous tree species. Confirming the trend, the Czech Republic has witnessed an increasing percentage of European beech (1% increase since 2010) (Ministry of Agriculture 2017). Supposedly, the numbers will increase continually. As a result, European beech will partially substitute languishing stands of Norway spruce (Lindner et al. 2010; Holuša et al. 2018). Some studies, however, point out European beech sensitive response to long-lasting drought (Jump et al. 2006; Geßler et al. 2007; Granier et al. 2007; Cavin & Jump 2017). In comparison to spruce stands, beech stands show greater success of natural regeneration (occurrence, density, growth) and adaptability to air pollution (Králiček et al. 2017; Slanař et al. 2017). The higher resilience and plasticity of the beech compared to spruce is caused by the annual replacement of the assimilation apparatus. However, during the long-term impact of pollution load the forest damage increased through the soil due to increased acidification, disruption of the sorption complex and decrease of mycorrhizal roots (Ling et al. 1993; Power & Ashmore 1996). In response to climate change, beech stands increase the frequency of seed years (Overgaard 2010). Growth processes of the tree species are also affected, its mortality increasing with increasing drought at lower altitudes, yet with the effect of prolongation of its lifetime cycle (Filippo et al. 2012).

As soon as the beginning of the 20th century, the first national parks began to emerge in Europe, together with increasing preferences for ecological approach to forests, which led to greater interest in close-to-nature forestry.
(Christensen et al. 2005). National parks, including our area of interest in the Krkonoše Mountains, took over the beech stands with their noteworthy history. From the 17th to the 19th century the beech stands were used as forest pastures and source of cattle feed – beech nuts (Nožička 1961; Lokvenc 1978). For many centuries, beech stands were also used for fuel wood and production of charcoal (Peters 1997). In recent decades, the health status and development of forest stands were damaged by synergic effects of air pollution load (acidification, ozone effect) and climate stress (extreme fluctuations, frosts, droughts, wind storms) (Bytnerowicz et al. 2007; Paolletti et al. 2010; Vacek et al. 2013, 2015a).

Together with industrial development and increasing air pollution after World War II, the first macroscopically visible large-scale damage to forest stands in the Czech Republic occurred (Materna 1989). Consequently, the most significant air pollution loads caused by high concentrations of SO2 were recorded in the Krkonoše Mountains in the 1970s–1990s (Bridgman 2002; Matějka et al. 2010; Vacek et al. 2010; Král et al. 2015; Vacek et al. 2017). Since the 1990s, NOx and O3 air pollution have also been perceived as a problem (Hůnová & Schreiberová 2012; Vacek et al. 2015a). Mankind has influenced forests throughout history, and on this basis it was found that 85% of beech stands developed in regeneration cycles of 15–25 years, with high-level regeneration in subdominant trees (Schütz 2001).

The Krkonoše Mountains stands were affected not only by air pollution loads but also by climatic factors such as ground frosts in 1977, wind disturbances in 2007 and 2008, or in increasingly frequent extreme droughts in recent years (Trnka et al. 2015; Bošeľa et al. 2016; Brázdil et al. 2017, 2018). Damaged by air pollution, forests were consequently infested with beech scale (Cryptococcus fagi /Baer./Doug.), followed by gummosis and more than often also by bark canker (Vacek 1988). Canker and necroses in beeches are most frequently induced by Nec- tria, Ophiostoma, Phomopsis and Verticillium pathogens, or some species of Phytophthora, fungi causing vast damage throughout Europe (Motta et al. 2003; Cicáč et al. 2006). Among other pests in the Czech Republic we can name beech-leaf gall midge (Mikolaj fagi Htg.), Bucculatrix ulmella Zeller and Ectoedemia lieberdollia Zimm. (Urban 2000; Miháll et al. 2014). All these abiotic and biotic factors affect the growth conditions of European beech stands on the research plot. Last studies bringing results of long-term research of natural beech stands in the eastern Krkonoše Mts. were published in 2010 and 2015, focusing on the European beech stand structure and the effects of air pollution (Špulák & Souček 2010; Vacek et al. 2015b), but no research on dendrochronological development of these unique forest stands has been published yet.

This study explores the potential of the cyclical dynamics of European beech in stands left to spontaneous development in conditions of the climate change and uses a dendrochronological analysis that combines the evaluation of frequency dynamics of the lower and higher “bandpass filtering” of dendrochronological series (Bunn & Mikko 2018a, 2018b). The study also evaluates the effect of monthly temperatures and precipitation on radial growth to differentiate responses to climate during a particular season (Biondi & Waikul 2004). Particular attention is given to clarification of the influence of climate change on natural beech stands in the eastern part of the Krkonoše Mountains National Park, which was left to spontaneous development in 1963.

2. Material and methods

2.1. Study area

The studied area of Boberská stráň (Rýchory Hills) is situated in the east of the Krkonoše Mountains National Park near the town of Žacléř, close to Poland frontier. Studied three permanent research plots (PRP 30, 31, 32) with similar growth conditions are composed by dominant European beech (99.8–100.0%) and admixed sycamore maple (Acer pseudoplatanus L.; 0.0–0.2%). Research areas are in the first zone of protection of the Krkonoše National Park at an altitude of 740–790 m a.s.l. on a northeast facing slope. The predominant soil type is the Cambisol with meta-diabase subsoil. The climate at the site is characterized by temperatures oscillating around 5.2 °C with an annual total precipitation of 870 mm. The growing season lasts about 120 days with an average temperature of 11.9 °C and a total precipitation of 640 mm. In Köppen’s classification, this is a damp continental climate with warm summers (Dbf) – (Tolazs 2007). Phytosociology defines the area as Fagion sylvaticae Luquet 1926, Eu-Fagenion Oberdorfer 1957 sub alliance and Dentario enneaphylli-Fagetum Oberdorfer ex W. et A. Matuszkiewicz 1960 plant association. In 1963, natural beech stands on the PRPs were left to spontaneous development.

The studied PRPs of 50 × 50 m (area of 0.25 ha) were established by Forestry and Game Management Research Institute, Forest Research Station at Opočno in 1980 to monitor long-term factors affecting the forest environment (Vacek 1988). Several measurements by technology Field-Map (Institute of Forest Ecosystem Research – Monitoring and Mapping Solutions Ltd.; IFER 2017) were carried out on these PRPs, studies of which were published (Vacek et al. 2010; Vacek et al. 2015b). This technology was used for repeated measurements of the positions of tree layer, dead wood and natural regeneration, tree heights, heights of the live crown base and crown projection areas together with the diameters at breast height (DBH). Fig. 1 illustrates the localization of natural beech forest stands on PRPs and Table 1 shows the basic site and stand characteristics of PRPs.
2.2. Data collection

For dendrochronological analysis, increment cores were taken from the European beech using the Pressler auger, perpendicularly to the stem axis, in the down-the-slope direction. Trees were randomly selected using the RNG selection (MS Excel); a total of 72 cores (24 per PRP) were taken from trees with DBH $>250$ mm. The analysis required 67 samples: 23 from PRP 30, 21 from PRP 31, and 23 from PRP 32. Cores were measured by an Olympus microscope on a LINTAB measurement table (RINTECH). The samples were measured from the bark to the heartwood, perpendicularly to the centre of the stem so that each ring was measured perpendicularly to the axis of the stem with an accuracy to hundredths of millimetres. Subsequently, the increment cores were crossdated in CDendro program (Cybis Dendrochronology), with the CC $>25$.

Climate data (monthly air temperatures and sum of precipitation) were taken from the nearest meteorological station of Pec pod Sněžkou (Czech Hydrometeorological Institute, Prague), 11 km from research areas at an altitude of 816 m a.s.l. ($50°41'30.480"$N, $15°43'43.320"$E). The range of climate data surveyed was set to the 1976–2017 period. Data on average annual temperatures, growing season temperatures, temperatures out of the growing season, temperatures in particular months and annual sum of precipitation, sum of precipitation in the growing season, precipitation out of the growing season, precipitation in particular months and precipitation in particular months were used to describe the development of temperature and precipitation conditions. The meteorological data source was provided by operator Czech Hydrometeorological Institute. Climatic data was archived by the National Climatic Data Center.

2.3. Data analysis

Dendrochronological analysis data were processed in the R (R Core Team 2018) program, using negative exponential detrending to remove the age trend of analysed increment cores with an inserted spline of 1/3 sample age. Consequently, the values were averaged by the chron function (Bunn & Mikko 2018b). To generate information for each chronological curve signal, dplR-packages for R and signal were used. A graph of single high-pass filter spectrum signal was created in period ranges of 1 to 20 years. Splines from 4, 8, 16, 32, 64 to 128 years were inserted to the average data curve to show significant events (Bunn & Mikko 2018a; Team R Core 2018). DendroClim 2002 (DendroLab) was used for the analysis of dendrochronological curves with monthly climatic conditions, utilizing the response and correlation function in the months from May to September (Biondi & Waikul 2004).

Data from the evaluation of diameter increment of beech in relation to climate factors were statistically processed by the Statistica 12 program (Statsoft, Tulsa). To determine the combined effect of average annual temperature and annual sum of precipitation on radial growth of beech, the regression quadratic model was used. The principal component analysis (PCA) was run in CANOCO 5 program (Lepš & Šmilauer) to assess the relation between the radial growth of beech forest stands, sum of precipitation and average temperatures all the year round, in the growing season (from April to September), out of the growing season (from October of the previous year to March of the current year), in June to July and in January to March of the current and previous year. Prior to the analysis the data were logarithmized and standardized. The results of multivariate PCA were visualized in an ordination diagram.

3. Results

3.1. Dynamics and frequency of radial growth

Detrended radial growth data series (Fig. 2) show that each stand on the studied PRPs developed differently. On PRP 30, no substantial drops in production were detected. This finding is also related to the fact that only five climatically significant years (12) were documented on the PRP until 1973. PRP 31, though, witnessed the highest number of climatically significant years (13) in terms of radial growth, and the increment varied significantly throughout the years. PRP 32 showed the most substantial cyclicity of radial growth and revealed five climatically significant years.

On Boberská stráň, beech stands generally show great plasticity of radial growth (Fig. 2). The analysis of climatically significant years since the mid-19th century for all PRPs shows major significances as late as in 2011, 2016 and 2017. During the 3rd to 8th May in 2011 the temperature was −8 °C, which these extreme late spring frosts damaged the fresh budding leaves and negatively affected whole growth of European beech in season 2011. The year of 2016 was specific for frost damage of the assimilation apparatus, serious infestation with beech-leaf gall midge and a significantly low precipitation of about 1 000 mm (300 mm below an average).

Forest stands on each PRP developed differently, while the longest, 17-year periodic growth cycle of beech occurred in PRP 31; the following cycles repeated every 2, 5, 6 and 7 years (Fig. 3). In PRP 30, the cycles repeated mostly in periods from 10 to 16 years. PRP 32 witnesses small cycles from 2 years and significant periods from 6–7, 10 and 18. Overall, in all PRPs, periods from 10 to 18 years prevail (Fig. 3).

3.2. Effects of temperature and precipitation on radial growth

In term of monthly air temperatures in relation to the average annual radial growth of beech, the growth responds positively in May of the previous year, where significant (P<0.05) values (r = 0.30 – 0.37) were found for PRP 30 and 31 (Fig. 4). Other significant months are January and February of the current year, when PRP 31 and 32 are significant (r = 0.23 – 0.42) and PRP 30 (r = 0.24) shifts the relation to February and March (i.e. by one month). In August of the current year, all stands on the PRPs (r = 0.28 – 0.44) responded significantly, with a longer response in PRP 32 – from July to August. In total, PRP 32 responds most significantly, followed by PRP 30, where a minor trend is apparent during growing periods, depending on the linear curve. All PRP stands show a rising positive trend of temperature effects in individual months (Fig. 4).

The effect of monthly sum of precipitation on the PRPs stands varies during vegetation periods (Fig. 5). The first significant month is August of the previous year,
when the negative correlation was significant only in PRP 32 ($r = -0.26$). January of the current year is another significant month, when the negative relationship in the stands on all PRPs was significantly demonstrated ($r = 0.18 – 0.23$). Positive correlation was found in March of the current year in stands on all PRPs ($r = 0.28 – 0.33$) and in February of the current year in the stand on PRP 32 ($r = 0.30$). Another significant negative correlation was found in July of the current year ($r = 0.20$). Overall, the growing season shows an increasing negative influence of precipitation on radial growth of European beech (linear curve of all the plots; Fig. 5).

3.3. Interactions between radial growth and climate

In terms of relationships between climate and radial growth presenting by PCA, the first ordination axis explains 32.7% of data variability, the first two axes together explain 50.0% and the first four axes 72.2% (Fig. 7). The x-axis illustrates the radial growth of beech with temperature parameters and the second y-axis represents the prevailing precipitation amount. Ring width index was positively correlated with temperature in January to March, out of the growing season and in the growing season of the current year, while temperature in the previous year had low effect on diameter increment. In terms of precipitation, the highest positive correlation of radial growth with precipitation was observed from January to March, out of the growing season and in the growing season of the current year, while temperature in the previous year had low effect on diameter increment. In terms of precipitation, the highest positive correlation of radial growth with precipitation was observed from January to March and out of the growing season of the current year, but these precipitations had small explanatory variable in the ordination diagram. Overall, the effect of temperature on increment was more significant than that of precipitation. Comparing similarity of growth on particular PRPs, diameter increment of beech on PRP 30...
and 31 was very close to each other compared to PRP 32. Species diversity diagram showed that years 2007, 2014, 2015 and 2016 brought the highest values.

4. Discussion

A standard dendrochronological analysis suggests that all studied PRPs showed increments of 0.4 to 1.4 RWI, which is close to the results obtained from the nearby Orlické hory Mountains, where the index reached similar values 0.4 – 1.6 RWI (Králíček et al. 2017). Foreign studies also show a similar range of values. For example, in southern Sweden, RWI ranges from 0.4 to 1.6 (Bolte et al. 2010).

The development of studied stands was affected by intensive thinning interventions in 1953 (on PRP 31 and 32) and 1954 (on PRP 30), in response to severe frost damage of the stands (beech crown breakage) at the end of winter 1952–1953. The ring series on studied PRPs also show a significant decrease in radial growth during 1975–1989, caused by effect of air-pollution load. Between 1980–1986 average SO$_2$ deposition from the EPO II thermal power plant in Poříčí reached to 59 µg m$^{-3}$, respectively seventeen times higher concentration than nowadays (Samec & Vránová 2005; Tesař et al. 2011). Air pollution impact on radial growth is well documented in Norway spruce in the Krkonoše Mountains and the whole Sudeten system (Kroupová 2002; Rydval & Wilson 2012; Vacek et al. 2013; Kolář et al. 2015), less in European beech (Vacek & Hejcman 2012; Králíček et al. 2017). In early spring 1981, beech crowns were heavily damaged by ice-load and, consequently, the assimilation apparatus of the trees suffered from frost. The air-pollution calamity in 1984 was followed by strong infestation with beech scale (Cryptococcus fagi) and beech-leaf gall midge (Mikia Luke fagi) (Vacek 1988). Furthermore, lower temperatures during the winter period in 1996 combined with the reverberating pollution load led to beech scale outbreak, recorded in other mountain regions of the Czech Republic as well (Králíček et al. 2017). A similar situation occurred in Europe in 1976 when beech scale along with extreme drought caused considerable damage and decreased radial growth of European beech (Wainhouse et al. 1988). Negative impact of beech scale on beech growth was also recorded in America (Gavin & Peart 1993; Kasson & Livingston 2009, 2012). To a lesser extent, ice-load induced crown damage repeated in winter 2004–2005. Above mentioned types of damage on many PRPs in the Krkonoše Mountains was reported by Vacek et al. (2007). Assimilation apparatus was severely damaged at the beginning of the vegetation period in 2011 and, less severely, in 2016. In respect to the economic function of studied beech stands until 1963, their development on all PRPs was different, which has also been confirmed (Kooijman et al. 2000).

A spectral dendrochronology analysis shows, in all PRP stands, 10 – 18 years’ cycles occurring in the largest frequency spectrum. Short, mostly 2-year cycles are usually rationalized by fructification and seed-year cyclicity (Övergaard 2010; Nussbaumer et al. 2018) or local climate particularities associated with fructification of European beech (Drobyshchev et al. 2010) or other events such as spring late frosts (Vacek & Hejman 2012). More significant cycles occur in 10 – 18 years’ periods, mainly due to repeated extensive harvesting or climatic extremes in given periods (Mausolf et al. 2018). However, detailed studies on cyclical growth of European beech in the Sudeten system are yet to be carried out.

The relation of European beech radial growth to monthly sum of precipitation was similar in all stands.
on the PRPs. Negative correlations were recorded in August of the previous year and in January of the current year. Positive correlations were observed in February and March of the current year. Statistically significant negative correlations were also documented in July and August of the current year. The results are comparable with Králiček et al. (2017), who present similar positive correlations until March and negative impact of precipitation on radial growth in July. In Sweden, European beech does not suffer from the lack of precipitation as much as in our country, but a minor positive effect of precipitation in early spring is detectable (Drobyshév et al. 2010).

The relation of radial growth of European beech to average monthly temperatures suggest the prevailing positive influence of temperatures, except in July of previous year. In rare cases, however, extreme frosts negatively affected radial growth in late spring (in 1996, 2011 and 2016). Similar events are reported by Vacek & Hejcman (2012) from the western parts of Krkonoše. In our study, the most significant month influencing radial growth was August in current year, similarily as in beech forests in Balkan (Tegel et al. 2014). A comparison of our results and the study of European beech from the Orlické hory Mountains (Králiček et al. 2017) shows that our results from the Krkonoše Mts. differ in these correlations by two months earlier. Also, the results of a study carried out in Turkey show a similar trend of a shift in Fagus orientalis (Küse & Güner 2012). In contrast to the Swedish growth conditions (Drobyshév et al. 2010), the correlation we have found is significantly positive.

The main climatic factor affecting the growth of beech trees in the studied montane localities is the positive effect of temperature. This was also observed by Vacek & Hejcman (2012) in beech stands at higher altitudes of the Krkonoše Mountains. On the contrary, at lower altitudes of the Czech Republic high temperatures were a limiting factor of growth, especially in the growing season (Remes et al. 2015). The altitude significantly supports the influence of climatic factors on radial growth; the positive effect of temperature on radial growth increases with the altitude, especially in June and July (Meyer & Bräker 2001; Andreassen et al. 2006; Hauck et al. 2012). A similar situation is reported from Germany and Italy, where the temperature had significant positive influence in May in montane areas (1560 m a.s.l.), while in the lowlands (420 – 450 m a.s.l.) the temperature in June had a negative impact on the radial growth of the beech (Skomarkova et al. 2006). In contrast, Opalająłowczarek et al. (2018) documented that the temperature from April to June is decisive for the radial growth in the mountainous parts of the Sudetes. The diameter increment is a slightly less influenced by precipitation, as described by regression quadratic model and PCA or foreign references (Ježík et al. 2016; Rohner et al. 2016). It can be assumed that the global warming and lack of precipitation will bring growth decline at lower altitudes and growth increase at higher altitudes in the centre of the beech distribution range (Penuelas et al. 2007; Kramer et al. 2010; Dulamsuren et al. 2017; Ruosteenoja et al. 2018). The trend is confirmed by gradual expansion of natural regeneration of beech in montane areas in recent years (Vacek et al. 2015c; Janík et al. 2016). Similarly, global climate change may lead to rapid decline in the growth of range-edge populations, consequent retreat of the beech distribution in southern Europe and conversely it spread to the north (Sykes & Prentice 1996; Jump et al. 2006). On the base of modern species distribution models, the ecological consequences of the range contractions would lead to serious nature conservation and forest management in future (Dyderski et al. 2018).

5. Conclusion

Growth and development of beech stands in the Krkonoše National Park is influenced by several abiotic (late frosts, droughts), biotic (beech scale, beech-leaf gall midge) and anthropogenic factors (extensive harvesting, air pollution load). The climatically significant years show that radial growth of the stands on the PRPs responded differently, but low temperatures during the growing season and lack of precipitation at the beginning of the year were the most important limiting factors. The overall effect of the average temperature on the beech diameter increase was significantly higher compared to precipitation. As regards the radial growth period, 2-year cycles were most often followed by cycles ranging from 10 to 18 years. Dendrochronological analyses of close-to-nature beech stands show us possible trends of their development in the ongoing global climate change, as European beech is considered to be one of the most important tree species in the Czech Republic.

Forest management scenarios modelling with morphological analysis – examples taken from Podpolanie and Kysuce

Abstract
Scenarios modelling offers to forest management an option how to envision complex future associated with various natural, social, or economic uncertainties. The challenge is what modelling method to choose as many methodological approaches to scenario building exists. Morphological analysis is a basic modelling method for structuring and analysing a whole set of relationships existing in multi-dimensional, non-quantifiable, and complex topics. Especially, its application is relevant when abstract policy or market-driven challenges need to be investigated. In this study, we demonstrated the usefulness of the morphological analysis with an example case taken from forest management in Slovakia. The use of the method has enabled, from a number of uncertain futures, to identify three possible, plausible and consistent future scenarios of possible forest management direction in the regions of Podpolanie and Kysuce. Additionally, the future scenario modelling as prognostic method of qualitative research supported by quantitative models or forestry DSS could introduce participation and more dimensions into forest management modelling. Thus, the future scenarios modelling offers new methodological possibilities to how to deal with increasing uncertainties associated with increasing demands for various ecosystem services or negative impacts of climate change, that forest management in Slovakia will face in the near future.

Keywords: forest management; future variations; coherence of scenarios; consistency matrix; cluster map

1. Introduction
Although the term “scenario” comes from the field of dramatic art, from a prognostic point of view, it is a method of predictive analysis to forecasting the future pioneered by Kahn (Glenn & Gordon 2009). Future scenarios, originally developed for military planning purposes and later adapted by business world, have emerged since the late 1990s as an important tool in environmental analysis and policy formulation (Evans et al. 2008). Scenarios offer an excellent option for how to deal with uncertain future for which we have to make decisions today. They do not forecast the future-the most probable one- but rather search for multiple plausible futures.

Scenarios have been also used in assessing future forest management, which faces uncertainties mainly associated with changing the climate, socio-economic conditions, or technological developments (Hoogstra et al. 2017). Therefore, in the forest management, the scenarios could be used for illustration of the trade-off between ecosystem services, evaluation of different forest management practices, and/or assessment of potential future developments (e.g. Nordström et al. 2013; Korosuo et al. 2014; Albert et al. 2015; Carlsson et al. 2015; Hengeveld et al. 2017). Future scenarios method is often used also as a means of communication in initiating discussions with the public and stakeholders (Gaßner & Steinmüller 2004). Wollenberg et al. (1999, 2000) identified future scenarios as a tool encouraging the cooperation of forest owners, managers and stakeholders. The scenarios can be implemented in a participatory manner as a workshop-based activity with the participation of forest owners, decision makers and other stakeholders. The method stimulate dialogue in the searching for barriers and driving forces of further development as well as in planning processes (Evans et al. 2008). In recent years, the forestry sector in Slovakia has to deal with changing climatic and environmental conditions and higher demands of the public for forest products and ecosystem services. So, future scenarios implemented by a participatory approach could be an...
appropriate response to the ever-increasing public call for sustainable forest management. What is also confirmed by the fact that public participation in sustainable forestry in Slovakia is still very formal and difficult (Kovalčík et al. 2012; Sarvašová et al. 2014; Sarvašová 2016).

The challenge for the scenarios modelling is how to capture the complexity of the world. In order to inspire and influence the decision making, scenarios must be sufficiently reliable and consistent. Many different methodological approaches to how to deal with scenarios modelling exist (e.g. Bishop et al. 2007; Amer et al. 2013), also with various application in the field of forest management (e.g. Hoogstra et al. 2017). Bishop et al. (2007) described eight general categories (types) of scenario modelling techniques including those that deal with dimensions of uncertainty - GBN matrix (Schwartz 1991) and morphological analysis. By applying of these techniques, the scenarios are constructed by first identifying the sources of uncertainty that are the basis for alternative futures, depending on how the uncertainties play out. While GBN matrix of four cells represents alternatively the four combinations of the poles of the two uncertainties, the morphological analysis matrix contains any number of uncertainties and any number of alternative states for each uncertainty. Morphological analysis allows to narrow down all possible combinations by deciding which combinations including uncertainties (factors) and alternatives (variations) are plausible and important in modelling consistent scenarios for the future (Heinecke 2006).

Although a large number of possible combinations can be considered as a disadvantage of morphological analysis, there are several sophisticated software tools overcoming the problem. Some of the best-known tools in the field of morphological analysis and future scenarios modelling are Morphol (Godet & Roubelat 1996), Casper (Eriksson & Ritchey 2002) Godet Toolbox (2003), Scenario Analysis Tool Suite (Dilek 2009) or Parmenides EIDOS tool suite provided by Parmenides Foundation.

The goal of this paper is to present an application of future scenario modelling technique – morphological analysis in the development of forest management scenarios in two Slovak regions of Podpoľanie and Kysuce. The uncertainties - drivers and barriers affecting forest management in both regions were derived with the help of participatory manner by in-person interviews and structural analysis presented in previous papers (Navrátil et al. 2016; Brodrechtová et al. 2018). In this paper we present the method of examining possible, credible and plausible future alternatives of these derived uncertainties. Attention is paid to the process of assessing the overall consistency and coherence of scenarios implemented with the strong support of analytical functions of Parmenides EIDOS tool suite. As the result, three possible future scenarios of forest management presented in a short description were developed for each region.

2. Morphological analysis in general

The general morphological analysis is a basic, conceptual (non-quantified) modelling method for structuring a conceptual problem space - called a morphospace - and, through a process of existential combinatorics, synthesising a solution space (Ritchey 2018). More precisely, the goal of the method is in identifying and structuring all possible factors and solutions for non-reducible, complex problem spaces that often include human behaviour and political aspects (Johansen 2018).

The morphological process characterized by repeated sequences of analysis and synthesis generally moves ahead in five distinct steps (Johansen 2018). The first one is based on the detailed formulation of the problem while acknowledging that a precise definition of the issue might be unlikely. Within the second step, the defined problem is split into factors that set boundaries to it. Each factor must be carefully selected and characterized by a set of possible variations. The third step is crucial as the morphological box is designed. This box also called multidimensional matrix represents all combinations of the factors and their variations. As some combinations are inconsistent or impossible-called also a problem space-, in the fourth step this space needs to be reassessed. In the search for a solution space, the consistency of the combinations is checked. Generally, consistency is assessed according to two criteria: (1) logical consistency- internal relations of the factors cannot be contradictory, and (2) empirical consistency- solution should not be empirically impossible (Amer et al. 2013; Johansen 2018). In the final fifth step the remaining solution space is surveyed and the best solutions - scenarios are selected.

Overall, Ritchey (2018) pointed the advantage of morphological analysis in recognizing new relationships or configurations, which may not be so evident and which we might have overlooked by less systematic methods. Importantly, it encourages the identification and investigation of boundary conditions, i.e. the limits and extremes of different contexts and factors.

3. Application of morphological analysis

3.1. Definition of the problem

As it is difficult to describe a future forest management in a holistic way, scenarios modelling has to focus on specific factors and omit issues that might be of relevance in other research contexts. In this respect it was essential to define the time horizon, the scenario-space via thematic coverage and the geographical scope (Greeuw et al. 2000; van Notten et al. 2003).

In the study we were concerned with assessment of possible future direction of forest management in the regions of Podpoľanie and Kysuce. Both case study areas (CSAs) represent traditional agricultural-forest regions in Slovakia with more than 50% of forest cover.
The territories have varied forms of land use such as forests, arable land, meadows, wetlands and dispersed as well as concentrated settlements. Significant parts of both regions belong to the network of protected areas. The forest ownership structure, health status, and current structure of forest stands are the biggest contrasts between the two CSAs. Considering the similarities and differences, the territories were chosen for application of future forest management scenarios modelling. Specifically, we described the forested landscape future and the development of the path from the present (2010) to the future forest management in 2040 while considering the influence of ecological, socioeconomic and political factors. Taking into account the comparatively slowly-changing system of forests the time horizon of 30 years can be considered as a short- or medium-term approach. The task was to create three possible, credible and mutually different future scenarios indicating possible forestry development over the next 30 years in each CSA.

The process was supported by Parmenides EIDOS tools suite offering several tools for analysis and scenarios building. The tool suite is used globally by public institutions in decision-making and strategic decisions, especially for complex processes requiring a multidisciplinary approach.

3.1.1 Case study area Podpoľanie

Case study area is located in the central part of Slovakia within Detva district. Podpoľanie is traditional agricultural-forest region with specific cultural landscape development characterized by dispersed rural settlements and traditional land use (e.g., small private owners). Due to very favourable climatic conditions, Podpoľanie region is one of the most productive forest areas in Slovakia. Especially upper part covered by beech, fir-beech and spruce forests is very productive. Forest stands are relatively healthy and stable with predominance of original tree species composition, but there are also stands with artificially inserted spruce. State forest ownership dominates (almost 85%), so State enterprise Forests of the SR is the strongest forestry entity in the CSA. From non-state subjects the biggest share has communal (8%), private and church ownership (3%), while the proportion of municipal forests is very small. The northern mountain area of the region dominated by the massif of Poľana Mt. is part of the Carpathian Arc. Due to the richness of fauna and flora (nearly 2700 species), this part of CSA is under the Poľana Protected Landscape Area. Moreover, more than half of territory (57%) is covered by NATURA2000 network. As the drink water reservoir Hriňová, located in CSA supplies drinking water to the surrounding cities, the water management function of the surrounding forest stands is equally important. Thanks to the Protected Game Area Polana, providing a coordinated ecological and large-scale management of the game, the region is known for its hunting tradition. The case study area is also intensively used for recreational activities such as hiking, mushroom picking, cycling as well as winter sports. For more information see also Navrátil et al. (2016) and Brodrechtová et al. (2018).

3.1.2 Case study area Kysuce

Case study area located in north-western Slovakia completely covers two districts – Čadca and Kysucké Nové Mesto. The rural population (56%) prevails in the region, inhabiting 37 mostly rural municipalities. The region represents an agricultural and forest landscape forested by coniferous forests (84%) mainly concentrated in the higher positions of the northern part of the territory. Almost half of the CSA belongs to the Kysuce Protected Landscape Area covering the northwest and northeast parts of the region. In the past the tree species composition in Kysuce has been significantly affected by the establishment of spruce monocultures. However, in the last decades the health of spruce forests in Kysuce has declined (e.g. Konôpka 2004; Kulla 2009) due to intensive and widespread necrosis (Hlásny et al. 2010; Bošela et al. 2014). This unfavourable situation causes frequent calamities, so the Kysuce belongs to the Slovak regions with highest volume of incidental felling (Vakula 2011). This situation mainly affects smaller non-state forest owners, as the forest ownership in Kysuce is highly fragmented with a large proportion of non-state owners (46%). The largest share has the private ownership (33%), followed by state (20%) and communal (13%). In addition, there is a large area of forests with unsettled ownership due to still ongoing restitution process (34%). For more information see also Navrátil et al. (2016) and Brodrechtová et al. (2018).

3.2. Characteristics of key factors and their variations

Identification and selection of key factors for the selected CSAs were based on the results of studies done by Riemer et al. (2013), Navrátil et al. (2016) and Brodrechtová et al. (2018). Within these studies, a wide group of drivers and barriers of forest management have been created at first. From this group, the set of relevant factors were identified and finally, key factors were isolated for each CSA.

The drivers and barriers have been analysed at the local level of CSAs, as well as at the national and EU levels. Their identification was based on primary data (structured in-person interviews) and secondary data (output of qualitative analysis of national and European documents). Brodrechtová et al. (2018) identified via 50 in-person interviews with forest owners, managers and other relevant stakeholders from Podpoľanie and Kysuce 22 drivers and barriers shaping forest management in
the future from the local perspective. More precisely, biophysical conditions and attributes of the community, including the political and economic context, institutions, and discourses, were among the significant drivers affecting forest owners and managers, and their interactions and decisions concerning forest management in the Podpoľanie and Kysuce (Brodrechtová et al. 2018). Secondary data were analysed in the form of desktop research. An extensive review of existing national documents (e.g. strategic and prognostic documents related to forestry, rural economy and the nature protection) resulted in the isolation of subset of 28 drivers and barriers, including bio-physical conditions and attributes of the community, political and economic contexts, and institutions that can potentially determine decisions concerning forest management in Slovakia (national level) (Navrátil et al. 2016). In addition, an extensive review of existing national documents and EU documents resulted into the isolation of 35 drivers and barriers representing EU level (Riemer et al. 2013).

From the group of 85 local, national and EU drivers and barriers Navrátil et al. (2016) identified 20 relevant factors for each CSA. Reduction was completed within an expert workshop (10 experts from Technical University in Zvolen and National Forest Centre). From the list of 85 factors, every expert chose 20 factors considered the relevance for the further development of forest management in the CSAs and sorted all factors by importance. To facilitate the listing procedure the factors were structured according to STEEP analysis that provides a useful framework to assist experts in the consideration of factors external environment (Zanoli 2012). Finally, the factors were evaluated by the frequency analysis, taking into account the frequency and ranking of the factors. The set of 20 relevant factors for each CSA was subsequently grouped according to STEEP categories (‘Society’, ‘Technology’, ‘Economy’, ‘Ecology’ and ‘Politics’) (Navrátil et al. 2016).

For the purpose of scenarios creation, it was necessary to reduce number of relevant factors. Thus, the key factors were identified first, from which the final factors used to construct scenarios were selected. For the isolation of key factors, the method of structural analysis (Glenn and Gordon 2009) supported by Parmenides EIDOS. The morphological box for scenarios created within Parmenides EIDOS. The morphological box for which at least two possible future variations are suggested. Furthermore, for each factor the possible, plausible and alternative future variations for the next 30 years were created by research team. Three basic requirements were taken into account: (i) the future variations should integrate the results of the structural analysis and the available scientific information on the individual key factors, (ii) the future variations should be as plausible as possible, and (iii) the future variations should differ in a meaningful way. Total set of 20 possible future variations of factors for Podpoľanie and 18 variations for Kysuce has been created. Description and characteristics of created variations are provided in Appendix A of this paper (Table A3, Table A4).

### 3.3. Design of morphological box

#### 3.3.1 Weights and probability of occurrence

Derived sets of key factors and their possible future variations represented individual dimensions of the future space of 30-year scenarios for Podpoľanie and Kysuce. Morphological boxes were derived by the research team in Parmenides EIDOS. The morphological box for Podpoľanie contained 8 factors and their 20 future variations (Fig. 1) while scenario’s space matrix for Kysuce was represented by 7 factors and 18 variations (Fig. 2).
The significance of the individual factors for future forest management in CSAs was assessed by research team members via the weighting factors (numbers in the top row) and the probability of occurrence of each variation was expressed in percentage (numbers in lighter boxes). The significance of the individual key factor was expressed by assigning the appropriate weights to each factor with the sum of weights being 100. The process was carried out in the framework of the discussion, using the expertise and knowledge base of the expert team, characteristics of factors and findings from previous research steps.

Each future factor’s variation was associated with probabilities of its occurrence in the future, based on the assessment how probable a variation is compared to the other alternatives in the scenarios space. Within the discussion research team members answered the question: What is the probability that a given variation occurs over the next 30 years? Then the probability of its occurrence in percentage was attributed to each variation, while the sum of the percentages of all variations within the factor was 100%. Due to its nature the given factor G1 – Forest ownership (in CSA Podpolanie) was associated with a 100% probability, as it was assumed that the owner’s structure would not change.

3.3.2 Consistency matrix

Within the created scenarios spaces the coherence of variations was assessed by defining relationships between the variations on the basis of internal consistency. The consistency was assessed by research team members during several brainstorming sessions with the support of Consistency Matrix tool of Parmenides EIDOS. The consistency matrix measures the logical fit of two variations. A higher consistency level indicates better coexistence of the two alternatives. A lower consistency rating indicates a greater degree of friction between the variations. Research team discussed and evaluated each variations pair by answering the questions: Do the two variations make sense together? How well or poorly do they fit together? The evaluation scale by Parmenides EIDOS was used (Table 2).

---

**Fig. 1.** Morphological box for Podpolanie.

**Fig. 2.** Morphological box for Kysuce.
Table 2. Consistency evaluation scale used for filling the consistency matrix.

-3 Complete inconsistency. Both projections exclude each other absolutely and cannot go together in a plausible scenario.
-2 Strong partial inconsistency. Both projections strongly contradict each other. Their common appearance affects the credibility of a scenario strongly.
-1 Light partial inconsistency. Both projections contradict each other easily. Their common appearance lightly affects the credibility of a scenario.
0 Neutrally or independently of each other. Both projections do not influence each other and their common appearance does not influence the credibility of a scenario.
+1 Light mutual support. Both projections can coexist easily in a scenario.
+2 Strong mutual support. Both projections can go together rather well.
+3 Very strong mutual support. The common appearance of both projections supports the strong credibility of the scenario.

The consistency values for each pair of variations were determined as a consensus after the discussion. In the case where it was really difficult to assess relationships of the variations, the neutral dependency was assigned (value 0). The consistency for all combinations of variations was assessed by filling the matrices for both CSAs (Fig. 3, 4). The direction of impact does not have to be taken into consideration, thus it was sufficient to fill the area above the diagonal in the matrix. The consistency calculation was carried out by means of Parmenides EIDOS. The software calculates with a full enumeration all possible scenarios combinations with their internal consistencies. In consistency matrices in both CSAs, the

Fig. 3. Consistency matrix for Podpoľanie (−3 complete inconsistency, +3 strong consistency).

Fig. 4. Consistency matrix for Kysuce (−3 complete inconsistency, +3 strong consistency).
most commonly assigned consistency value was 0 (37% in Podpolanie, 25% in Kysuce), followed by +1 (20% in Podpolanie, 22% in Kysuce) and −1 (18% in Podpolanie, 21% in Kysuce). The predominance of combinations ‘neutrally or independently’ (value 0) meant frequent occurrence of projections that do not affect each other but also the fact that it had often been difficult to assess the relationships of the variations.

3.3.3 Cluster map

Subsequently, clustering of coherent combinations of possible variations (scenarios) was carried out by Cluster Map tool of Parmenides EIDOS. The calculation was based on the number of factors and their assigned weights, a number of variations, their probabilities and consistency degrees assigned in consistency matrix. The cluster map displayed generated scenarios in two-dimensional distribution built up on their similarity and overall consistency. The cluster view is based on a complex projection algorithm and shows the 100 most consistent scenarios on a cluster map pooling single scenario (shown as circles) to clusters according to their similarity. The closer the circles that represent scenarios are, the more similar are the scenarios; the farther they are apart, the more different they are.

Internal consistency of scenarios is expressed by size of the circle in the map. The larger circle, the more internally consistent scenario and vice versa the small circle means a scenario with a small internal consistency. Calculation of overall degrees of consistency of individual scenarios was done by Parmenides EIDOS using scaled pairwise consistency assessment, where a weighting function assigns numerical values to the Likert-levels and the average of the consistency values of the involved tuples is calculated (Kempf 2015). Degrees of consistency (dimensionless numbers) represented overall

Fig. 5. Cluster map, morphological box, consistency degrees, probabilities and marked selected scenarios for Podpolanie.

Fig. 6. Cluster map, morphological box, consistency degrees, probabilities and marked selected scenarios for Kysuce.
internal consistency of individual scenarios and helped in selecting scenarios, since scenarios of greater consistency are of interest.

The probability of occurrence of the scenarios was carried out by Parmenides EIDOS using the probabilities of the individual variations defined in the morphological box. The scenario probability was expressed by the number of “+” marks associated with the scenario. A range of 0 (lowest probability) to 8 (highest probability) marks has been used.

From 8 factors and their 20 variations, a set of 972 possible future scenarios have been derived for Podpolanie. It can be clearly identified in the cluster map (Fig. 5) that all possible scenarios are redistributed into four main groups of clusters. Scenarios concentrated close together in a cluster were meaningfully similar to each other. Since the goal was to select mutually different scenarios, the focus was mainly on different clusters. A ranking procedure by degrees of consistency was applied to identify scenarios which are particularly consistent. Calculated consistency degrees of scenarios ranged from 0.1 (lowest consistency) to 1.09 (highest consistency). Most of the 972 scenarios had a low degree of consistency, with only 65 had the consistency degree greater than 0.5.

In Kysuce, a combination of 7 elements and their 18 manifestations, resulted in a set of 648 possible future scenarios (Fig. 6). At least five main groups of clusters could be identified in the map. Probabilities of occurrence, as well as consistency degrees, reached higher values compared to Podpolanie. The consistency ranged in 0.2 to 1.75 and 25 scenarios had consistency degree greater than 1.0.

3.3.4 Selection of final forest management scenarios

The final selection of scenarios for both CSAs was done by the research team during several brainstorming sessions. As the result, the three scenarios of possible future development of forest management in Podpolanie and Kysuce regions were selected (Table 3, 4). The process was supported by Parmenides EIDOS but the decision was reached by a consensus of team members. The choice of scenarios was determined by three criteria: consistency, diversity and plausibility. Cluster maps displaying the scenarios in a cluster view were used to ease the selection. To avoid selecting several scenarios that are simply slight variations on the same theme, distinct clusters were identified at first. This has ensured the diversity criterion to select scenarios each other meaningfully distinguished. Then we looked for the most consistent scenarios in the cluster. The more consistent scenarios were, the bigger they were displayed in the cluster map. The ranking by consistency degrees showed scenarios with the high consistency, but the order itself was not a decisive criterion because it does not take into account diversity of scenarios. That’s why the combination of cluster map visualisation and consistency degrees was used for the selection. To obtain reasonably likely scenarios the probability of their occurrence over the next 30 years was considered. Scenarios marked with 0 or 1 “+” were excluded from the selection. We have focused particularly on scenarios with 4 and more “+”. But, as can be seen (Table 3, 4) the most consistent scenarios in both CSAs had a probability of only 2 “+” or 3 “+” respectively. Considering the highest consistency and focus of these scenarios, the lower probability was accepted by the research team. This shows that despite strong software support, the final decision was on the research team that took into account all the information gathered during the all research phases.

4. Features of selected forest management scenarios

As a result of the morphological analysis process, three selected scenarios of possible future development of forest management were identified for each CSA. These scenarios meet the requirement of internal consistency, are meaningful, probable and mutually different. Each scenario was created by combining selected variations that define the scenario itself (Table 3, 4). For scenarios, the brief basic descriptive features that are presented in this chapter have been created.

Scenario 1: Improved state of forests and increased wood demand

Full use of the natural production potential of forests in Podpoľanie is predicted. Such maximal utilization will also be supported by the application of short-term rotation forestry under preservation of the sustainability and ecological stability of forests with less emphasis on the provision of other ecosystem services. Lessening the impact of climate change and ecological disturbance is awaited. Health conditions and ecological stability of forests will stay on the current level, respectively will be improved. Strong political enforcement of the economic interests of forest owners over the interests of nature conservation is expected. Despite a harmonization of environmental and forestry policies, the forest law will be more strongly enforced as a law on nature conservation. Growing wood demand is estimated due to new investments in timber processing capacities and/or due to increased support of energy from renewable resources, particularly from biomass. Lower societal demands for the fulfillment of other ecosystem services are expected. It will lead to a reduction in the extent of forest protection and biodiversity conservation.

Scenario 2: Fear for forest sustainability

Applying measures to systematically enhance the sustainability and ecological stability of forest stands in Podpoľanie is expected. The measures will be applied in combination with strengthening the provision of selected non-production ecosystem services (water, recreation, hunting, research function), which will be complemented by secondary wood and biomass production. Increasing the negative impact of climate change and ecological disturbances on forest stands are anticipated. Effective forest management, mainly focused on the production function, in practice will not be possible or will be significantly limited. Increased efforts by forest owners for income outside the forest are foreseen. The incoherence of forestry and environmental policy will persist, but as a result of social pressures, the importance of sustainable management is expected to increase, which, on the other hand, will enhance the protection of nature and biodiversity.

Scenario 3: Biodiversity maintenance – Growing societal demand for nature conservation

The dominance of nature and biodiversity protection, expanding the provision of certain non-production ecosystem services (recreation, water, research) is foreseen in Podpoľanie. Passive forest management is expected, coupled with strong restrictions on any active interventions (minimizing the provision of production functions and hunting). The strong demand and interest of society will lead to the strengthening of nature conservation legislation in favour of the economic interests of existing forest owners. Misunderstandings between foresters and
environmentalists in the region will be resolved in favour of the environmentalists. The state will either completely purchase forest land from small owners or will be willing to pay full compensation for the restriction of forest management.

4.2. Selected scenarios for CSA Kysuce

Scenario 1: Transformation of ownership and change of the forest management objectives

In the 30-year time horizon, the existence of large areas of even-aged mixed coppices formed naturally is expected as a result of the predicted collapse of large complexes of unnatural spruce stands in Kysuce. Ecological stability of dense and even-aged forest stands may not be fully satisfactory due to the increasing cost of stands tending. At the same time, the revenues from timber production will be significantly reduced due to the unfavourable situation in the domestic and foreign markets. It is assumed that small private forest owners will sell their land to bigger investors because the income from the forests will be significantly lower and no more subsidies are expected to be provided. In addition, due to rising forest management costs of forest land of unknown owners as well as due to growing political and social pressure, the state will be forced to address the issue of forest land of unknown owners. The same or rising demand for pulp and new biomass requirements for energy purposes are foreseen.

Scenario 2: Rural development and agroforestry landscape use

Expansion of the rural development policy, supported by a sufficient amount of subsidies is expected in Kysuce. It is supposed that this will lead to the preservation of the fragmented forestry agrarian landscape. The number of subsides will be sufficient for the preservation and development of agricultural activities, as well as on developing the use of biomass in the forest sector. The fragmented nature of the land ownership will be preserved, because of forest owners regardless of the situation on in timber and biomass trade, will be financially motivated to maintain the current forestry agrarian character of the landscape. It is expected the adoption of new legislation promoting the production of biomass and forest management. Biomass from increased production areas will be effectively exploited the growing bioenergy sector. Furthermore, these processes supported by subsidies will lead to job creation and to meeting the demands for skilled labour.

Scenario 3: Depopulation and landscape afforestation

Lack of subsidies and limited timber production will further increase the depopulation of the Kysuce and cause a massive reduction in non-economic agrarian and forestry activities. Extending the successive development of ecosystems on abandoned agricultural land and self-devel-

5. Discussion and conclusions

The future forest management could be driven by many factors and their variations, yet their combinations would deliver many scenarios. The morphological analysis offers systematic approach and helps to deal with the complexity that consists of a set of relationships, multidimensional and non-quantifiable problems challenging forest management. In this study, we have shown its applicability in forest management scenario modelling with an example taken from forest management in two traditional agricultural-forest Slovak regions. This specific qualitative approach of diagnostic method of future scenarios was used for the prediction of forest management development probably for the first time in the conditions of the Slovak forestry.

In the paper, the created scenarios are presented in the form of a brief description of the situation that can occur in 30 years. These scenarios can serve as a driving scenarios for further steps toward the final decision scenarios. Schoemaker (1995) called these scenarios Learning scenarios that help outline the boundaries of further development and identify themes that are strategically relevant in each case study area. They become the basis for further research to organize the possible outcomes and trends around these themes. While the Podpoľanie region was particularly concerned with the possible implementation of the forestry or nature conservation paradigms, the scenarios in the Kysuce region were mainly concerned with the topic of the ownership structure and its impact on forest ecosystems.

As learning scenarios are results of qualitative approach, the further research could be focused on quantitative models' implementation or evaluation of stakeholder's behaviours in given scenarios. By implementing forestry Decision Support Systems or growth simulators e.g. Silva (Pretzsch et al. 2002), Sibyla (Fabrika 2007),
Heureka (Heureka 2010) or Optimal (Marušák 2015) to the trends set in the individual scenarios, it is possible, for example, to quantify the fulfillment of ecosystem services in forest ecosystems in each region. The modelling can include simulated behaviour of forest owners and stakeholders, and various forest management measures correlating with the theme of the scenarios. The quantification of the consequences of various scenarios significantly enhances the credibility of the scenarios and allows them to be further extended as narrative scenarios into stories. Such scenarios can be further used in decision-making processes, for example, using the backcasting method (Wilson et al. 2006) exploring the feasibility of desirable futures set in scenarios.

Implementation of the whole scenario modelling process has been a challenge for the research team. Our experience has shown that the method cannot be realized by an individual, but the process requires experienced teams capable of assessing socio-economic, technological and environmental or policy aspects of forestry issues. The steps of scenarios’ consistency and credibility assessment were carried out in a number of iterations, using the brainstorming, discussion and consensus. Evans et al. (2008) called this process as a mental exercises to consider plausible, future situations, imagine potential outcomes and explore contingencies. Parmenides EIDOS toll suite was very helpful throughout the modelling process. The software provided flexible tools for scenario’s spaces management and visualisation that facilitated and clarified the whole process. However, like suggested by Gausemeier et al. (2009) the choice of final scenarios was supported by software, but not determined by it.

In the study, we used the participatory approach in particular in the initial phases of modelling scenarios; in-person interviews and structural analysis involving forest owners and stakeholders helped to isolate the crucial factors that later became the basis for scenarios. Based on our findings, it is advisable to involve forest owners and other stakeholders also in the process of consistency assessment itself. The process could be done by adding another participatory workshop where participants would jointly assess the morphological box, fill out the consistency matrix and judge the created set of scenarios. Stakeholders would discuss and evaluate the consistency of each variation pair. Weccard (2012) suggested to display on a screen two newspapers with a different top headline, that are the names of a variations from the variation pair and ask participants How do the two headlines make sense together? By using attractive visualization tools of Parmenides EIDOS, stakeholders could discuss and identify their preferred scenarios or scenarios they would like to avoid. Through joint consensus, they would be involved in planning the future direction of forest management in their region. The selection of workshop participants is crucial in order to achieve relevant results. It is important to involve relevant decision makers, experienced and informed owners and stakeholders with the relation to the region representing all relevant stakeholder groups. Engaging the same stakeholders as in earlier steps of the scenario making process can guarantee their interest in issues of forest management in their region. Beside this, the whole research team must also be involved in this kind of workshop, with the facilitator’s role in managing the productive discussion very important.

Our experience demonstrated that the morphological analysis supported by Parmenides EIDOS is a useful method for forest management modelling challenged by many factors (e.g., forest policy, forest owner’s behaviour) that by their nature are not applicable for analysis via deterministic or probabilistic methods (e.g. Ritchey 2011, 2015). As scenario studies concerning forest management have rather quantitative, non-participatory, or single factor in nature character (Hoogstra et al. 2017), an application of qualitative future scenarios method enriched by a quantitative model can introduce the use of the mixed-methods and participation into forest management scenarios modelling in Slovakia. Such forest management scenarios modelling carried out in a participatory manner may be considered a means to improve collaboration and promote dialogue among forest owners, other forestry stakeholders and the general public as well. Additionally, participatory scenario modelling workshops might increase the stakeholders’ interest in engaging in forest management planning processes, as this method is systematic, interesting and productive.

<tbody>
<tr>
<td>U1</td>
<td>State of forests</td>
<td>Up to 90% of forest stands in CSA represent mixed forests of temperate climate zone. Tree species composition is made up mainly of spruce (61.9%), beech (30.7%), fir (1.5%) and oak (0.5%) (Tuček et al. 2015). Due to very favourable climatic conditions, the CSA is one of the most productive forest areas in Slovakia. It is dominated by intensely-cultivated even-aged stands in which mainly shelterwood silvicultural system with an emphasis on natural regeneration is applied. Despite the occurrence of calamity felling in the CSA, forest stands are relatively healthy and stable. The original tree species composition is predominant, but there are also forest stands with artificially inserted spruce.</td>
</tr>
<tr>
<td>U2</td>
<td>Policies and legislation</td>
<td>Policies and legislation is a complex issue. Different parts of the legislation can affect the forest management in different ways. The main factors are: laws and regulations, standards, norms, rules, and informal institutions. The policies incoherence situation is significant in Podpolanie, where a state forest ownership structure prevails and large protected areas exist (Brodrechová et al. 2018). Compensations for financial loss due to nature protection restrictions is also problematic. Up to 90% of forest stands in CSA represent mixed forests of temperate climate zone. Tree species composition is made up mainly of spruce (61.9%), beech (30.7%), fir (1.5%) and oak (0.5%) (Tuček et al. 2015). Due to very favourable climatic conditions, the CSA is one of the most productive forest areas in Slovakia. It is dominated by intensely-cultivated even-aged stands in which mainly shelterwood silvicultural system with an emphasis on natural regeneration is applied. Despite the occurrence of calamity felling in the CSA, forest stands are relatively healthy and stable. The original tree species composition is predominant, but there are also forest stands with artificially inserted spruce.</td>
</tr>
<tr>
<td>U3</td>
<td>Timber/Bioenergy market</td>
<td>Many municipalities, towns or companies and industrial plants with biomass heating plants in Slovakia are using forest biomass. The policies incoherence situation is significant in Podpolanie, where a state forest ownership structure prevails and large protected areas exist (Brodrechová et al. 2018). Compensations for financial loss due to nature protection restrictions is also problematic.</td>
</tr>
<tr>
<td>U4</td>
<td>Forest owner’s economic situation</td>
<td>The economic situation of forest owners is significantly influenced by the forest management costs associated with forest management and its planning. There are several types of costs that affect the economic situation of forest owners in CSA. Firstly, the costs associated with the inconsistency of policies and the bureaucracy directly affecting forest management measures. In the CSA, where more than 50% of the area is under the nature and landscape protection, the inconsistency and contradiction of forestry and environmental legislation are well demonstrated. Unclear procedures for liquidation of various calamities in forests (especially in protected areas), restrictions on the implementation of silvicultural measures create additional costs for forest management. The policies incoherence situation is significant in Podpolanie, where a state forest ownership structure prevails and large protected areas exist (Brodrechová et al. 2018). Compensations for financial loss due to nature protection restrictions is also problematic.</td>
</tr>
<tr>
<td>U5</td>
<td>Non-wood ecosystem services</td>
<td>The main important non-wood ES in CSA are Biodiversity Maintenance, Water Regulation/Clean Water, Recreation/Tourism and Hunting. The richness of the fauna and flora of CSA represents nearly 2700 species, of which 310 are protected by national legislation. The 174 bird species were identified and 128 nested in the territory. 32% of the region is part of the Polana Protected Landscape Area and 62% belongs to the NATURA2000 protected areas network (Tuček et al. 2015). Drink water reservoir Hriňová, located in CSA serves as a reservoir of drinking water for the water supply system of surrounding cities. Thus, the most of the surrounding forest stands fall within the category of Special purpose forests with prevalent water management function. Management of such forests requires special treatment in order to ensure purity of the water source. The CSA is well known for its hunting tradition. The Protected Game Area of Polana (area of more than 20 000 ha) provides a coordinated ecological and large-scale management of the game. In addition, forests are used intensively for picking mushrooms and berries. Recreational activities, including hiking, cycling and winter sports, are also popular. Environmental restrictions significantly affect the forest owners and have a rather braking effect.</td>

Environmental restrictions significantly affect the forest owners and have a rather braking effect.</td>
</tr>
<tr>
<td>U7</td>
<td>Codes of conduct</td>
<td>Lack of financial resources is the main obstacle to the innovation process in forestry in Slovakia. Most forestry enterprises use subcontractors for silvicultural and harvesting operations. Due to short-term contracts, subcontractors face problems in fleet and mechanization renewal through loans, leasing, and so on. It affects the quality of the works carried out. The usage of obsolete machinery for working in forests has a negative impact on the environment as well. Due to the lack of funds, some forest enterprises do not perform silvicultural measures what may negatively affect the stability of forest ecosystems. Insufficient investments in the development and maintenance of forest road network influence the usability of felling-transport technologies and the overall cost. Overall, the innovation process in forestry stagnates and the transfer of the latest knowledge and research results into practice is still missing. The innovation cycle is too long, there is a lack of productive cooperation between research institutions and practice.</td>
</tr>
<tr>
<td>G1</td>
<td>Forest ownership</td>
<td>Ownership of the forest land in CSA is split between state and non-state forestry entities. State enterprise forests of the SR manages almost 85% of forests in the CSA. Thus, it is the strongest forestry subject in CSA. The largest share of non-state forest owners has communal (8.3%) and private (3.2%) ownership types. There is only a small part of municipal forests, church forests or forests still in the restitution process (unsolved ownership).</td>
</tr>
</tbody>
</table>
Table A2. Key factors used for designing the scenario space for CSA Kysuce.

<table>
<thead>
<tr>
<th>Code</th>
<th>Key factor</th>
<th>Factor description</th>
</tr>
</thead>
<tbody>
<tr>
<td>U1</td>
<td>State of forests</td>
<td>Kysuce belongs to the Slovak territories with high forest cover and prevalence of the spruce. In the past, large spruce monocultures were established in the region, often even in places not suitable for spruce. Such stands have a low degree of ecological stability as well as resistance to harmful factors. Lately, the area had been extensively affected by widespread necrosis of spruce stands (Kulla et al. 2009, Bošeľa et al. 2014) due to various abiotic, anthropogenic and biotic harmful factors such as honey fungus (Armillaria) and aggressive species of bark beetles (Hášny &amp; Sitková 2010). These factors caused, that in 2010, the region was the area with the largest volume of calamity felling in Slovakia (Václav 2011).</td>
</tr>
<tr>
<td>U2</td>
<td>Forest ownership</td>
<td>Forest land ownership in CSA is characterized by very high fragmentation: state forest owners (19%), forests still in restitution process (unknown owners) managed by State enterprise Forests of the SR (34%), and non-state forest owners including private, communal, municipal and church owners (46%) (Navrátil et al. 2016). The restitution process, which began in 1991 has not yet been completed. Although the management of such forests is provided by state foresters, this situation causes many problems. For instance, highly fragmented forest ownership structure means a divergent interest of forest owners, various expertise and experience, management approaches, traditions, different financial options, human qualities or relationship to the forest.</td>
</tr>
<tr>
<td>U3</td>
<td>Subsidies</td>
<td>Most financial instruments for agriculture and forestry originate from EU Rural Development policies. Specifically, via Rural Development Programme in SR for periods 2007–2013 and 2014–2020 should be achieved: (I.) improvement of the competitiveness of agriculture, food industry and forestry by promoting restructuring, modernization, development and innovation, (II.) improving the environment and the quality of life in rural areas, and (III.) promoting diversification of economic activity. Financial resources from the EU Structural Funds are also an important financial instrument for innovations. These resources are almost unattainable for many small private forest owners in CSA due to bureaucracy and administrative burden. They sensitively perceive the incoherence of forestry and environmental legislation as well as unclear legislation on subsidies and financial compensation (Tuček et al. 2015).</td>
</tr>
<tr>
<td>U4</td>
<td>Forest owner’s economic situation</td>
<td>The economic situation of forest owners is significantly influenced by the forest management costs associated with forest management and its planning. There are several types of costs that affect the economic situation of forest owners in CSA: (1.) Costs associated with the critical health status of spruce forests in the region, the effects of harmful factors and spreading of bark beetles. The high proportion of incidental felling, on one hand, increases a one-off income of forest owners. However, the income is lower because the wood is sold at lower quality. At the same time, problems are expected in the future, because of the lack of forest stands for logging. (2.) Total operating costs associated with the practical implementation of forestry measures. (3.) Costs associated with the inconsistency of forestry and environmental policies and legislation (e.g. unclear procedure for the liquidation of various calamities in forests located in protected areas).</td>
</tr>
<tr>
<td>U5</td>
<td>Timber market</td>
<td>Due to the high rate of calamity felling, excessive logging and high demand for wood in recent years, it is expected that the total felling volume in CSA will be reduced by 2030 due to lack of wood. Since the sale of wood is the most important source of income for the forestry sector, it will have a significant impact on the regional forestry enterprises, wood-processing companies, the overall forest management and measures in CSA. Additionally, economic performance will depend on the demand for fuelwood and biomass as well as on political development.</td>
</tr>
<tr>
<td>U6</td>
<td>Innovation and technology</td>
<td>In the majority of forestry enterprises in CSA, machinery equipment for the mechanization of harvesting and wood transportation does not correspond to still increasing demands for the reduction of negative environmental impacts. This is also reflected in the less of the logged timber and poorer quality of assortments, which in turn leads to increased operating costs and reduced income. A high proportion of calamity felling has another significant impact on applied harvesting technologies. Insufficient density and quality of forest road network causes an increase of skidding distance, what determines the usability of felling-transport technologies and affects the overall cost. By the majority of forest managers, the lack of financial sources is perceived as a main barrier in the innovation process. There is a mutual interaction between technological equipment and the level and quality of forestry measures implementation.</td>
</tr>
<tr>
<td>U7</td>
<td>Population</td>
<td>Demographic development of last decades in Slovakia mirrors the EU trend of decreasing birth rates and a decline in mortality. In CSA, the population census in 2011 showed population decline for the first time in census history (~ 1.2% in Čadca district and ~ 1.6% in Kysucek Nove Mesto district). The decline is due to an increased share of older people in the population while reducing the proportion of young people and people of working age. In Žilina the ageing index increased in period 2001–2011 from 52.9 to 74.9 and for Kysucek Nove Mesto district rose to 76.3 (Tuček et al. 2015). Since the trend in demographic transition and ageing is likely to continue, it will bring challenges concerning the availability of a qualified workforce in the region. The reasons behind are twofold. First, the employment in agriculture, forestry and fisheries at the national and regional level is becoming less attractive. Second, in the population engaged in agriculture and forestry higher average age and lower qualifications dominate.</td>
</tr>
</tbody>
</table>
The dominance of biodiversity maintenance
Importance stagnant
Importance increasing
Fluctuating
Favourable
Timber decreasing and Bioenergy stagnant
Biomass demand growing
Timber/Bioenergy demand growing
The price of input resources is increased twice as fast as production price causing pressure on the effectiveness of the wood processing industry.
As banks perceive the wood processing industry as risky investment sector, no new investments are planned and lack of wood processing capacities expected.
Stagnant demand for biomass due to stagnant fuels and energy prices and weak legislative and subsidies support for biomass.

Key factor U2: Policies and legislation

Predominance environmental policy

Strong societal demands lead to enforcement of legislation favouring entire societal interests for nature conservation over the economic interests of current forest owners.
Introduction of legislation significantly increasing financial resources for nature protection management.
Forest management activities of state and non-state forests owners are limited.
Compensation for financial loss due to nature protection restrictions entirely paid to forest owners.

Predominance forest policy

Strong political enforcement of the economic interests of forest owners over the interests of nature conservation. Despite partial harmonization of policies, forest law takes over nature protection law.
The forestry paradigm based on multi-purpose sustainable forest management, aimed at maximizing the volume production, even-flow and sustainable felling by sustaining other non-productive functions of forests is politically enforced.

Policies incoherence

Discrepancies between foresters and environmentalists are even getting worse.
Consistent lack of finances for protected areas management and compensation for financial loss due to nature protection restrictions. The State’s obligation to compensate financial losses to forests owners thus remains declarative.

Key factor U3: Timber/Bioenergy market

Biomass demand growing

Rapidly growing demand for biomass due to rising prices of basic fuels and energy.
Growing number of municipalities and companies equipped with biomass heating systems.
Introduction of legislation fostering the biomass production on unused agricultural land and the establishment of energetic forest stands.

Timber/Bioenergy demand growing

Growing timber demand due to the renaissance of wood processing and pulp/paper industry.
Fostering the green economy (green buildings; higher use of wood beams; improvements in the use of composite materials) is driven by the higher support of innovations and competitiveness.
The persisting strong interest in biomass among the population and a growing number of municipalities with biomass heating systems.

Stemming decreasing and Bioenergy stagnant

The price of input resources is increased twice as fast as production price causing pressure on the effectiveness of the wood processing industry.
As banks perceive the wood processing industry as risky investment sector, no new investments are planned and lack of wood processing capacities expected.
Stagnant demand for biomass due to stagnant fuels and energy prices and weak legislative and subsidies support for biomass.

Key factor U4: The Forest owners’ economic situation

Favourable

Better availability of subsidies through Rural Development policies as well as new supporting schemes introduced.
The positive trends in timber and biomass markets result in increased income for forest owners.
Better accessibility of compensation for financial loss due to nature protection restrictions and/or fulfilment of other ecosystem services.

Fluctuating

Fluctuating trends timber and biomass markets cause unstable income for forest owners.
Stagnant improvements in policy coherence and/or continuing only declarative character of Rural Development policies.
Unclear subsidies scheme insecure forest managers and do not allow longer-term financial planning.

Unfavourable

Income from timber and biomass production is limited.
Increased incoherency of forest and environmental policies and persisting absence of mutual cross-sectorial coordination.
Weak accessibility to EU structural funds due to bureaucracy and administrative complexity.

Key factor U5: Non-wood ecosystem services

Importance increasing

Increased broad societal pressure to foster sustainable forest management, greater emphasis on non-production ES and also to enhance the biodiversity and nature protection as a whole.
Non-wood ES becoming more attractive to forest owners, as a potential source of diversified income.
Growing importance of clean water as a strategic resource causes the spreading of special purpose forests around the water reservoirs Hriňová and Málinec.

Importance stagnant

Importance of ES reflects the present situation as there is a weak societal demand to change.
The tourist infrastructure development is very weak, so the region’s tourist potential is more-less stagnant.

The dominance of biodiversity maintenance

Policy instruments fully enforce the environmental paradigm that the natural evolution of the ecosystems is homeostatic and the best way of ensuring the ecological stability of the forests is the strengthening of their biodiversity. Production ES are subdued and the preference is given to nature conservation.
Passive forest management is associated with the strong limiting of any active forest management measures.
Compensations for financial loss due to environmental restrictions are entirely paid to forest landowners.

Abstract
Phenotypic plasticity of 22 spruce provenances in three test plots located in the European North of Russia was studied. Parent spruce stands are located within the Russian Plain and are represented by *Picea abies* (L.) Karst., *P. obovata* (Ledeb.) and two introgressive hybrids. In the test plots located in the middle and southern taiga subzones *P. abies* provenances are tested northward of its distribution area and *P. obovata* provenances are tested within the distribution area and nearby its boundaries. phenotypic plasticity of the spruce provenances was assessed. Straight-line regression coefficient based on survival, diameter, and height was calculated. All provenances are divided into two groups: plastic and non-plastic provenances. High plasticity is observed more often for *P. abies* and hybrids forms with properties of *P. abies*. Plastic provenances based on three parameters grow in the Leningrad, Pskov, Vologda, Kostroma and Karelia. Area of parent stands growing is quite small-size and lies between 56º30´ – 61º40´ N and 30º30´ – 42º30´ E. Adaptive provenances of *P. obovata* and its related hybrids forms grow in the North-Eastern part of the Russian Plain that could be consequence of its distribution in Holocene. *Picea abies* being the more adaptive species would be more responsive to climate changes in terms of survival and growth rate than *P. obovata*. Therefore, in case of sustainable climate warming in the Northern areas of the Russian Plain, the further propagation and major distribution of *P. abies* with further competitive replacement of *P. obovata* can be expected.

Key words: *Picea*; provenance test; survival; growth; phenotypic plasticity

1. Introduction
Provenance tests have more value in gen-ecological studies. Provenance trials contain large-scale genetic resources *ex situ* concentrated within small-size areas. They are objects of genetic monitoring (Iroshnikov 2002) providing multivariate stationary studies and assessment of provenances adaptive capacity based on their age and ecological stability (Rone 1979).

At present, it is considered that provenance trials can be used not only for provenances selection for the purpose of reforestation in certain regions as well as for seeds transfer. These experiments can be used for study of species history and their distribution within a certain territory (Lindgren & Persson 1995), for study genetic variations and migration (Potokina et al. 2015). A provenance trial can be used as a model for prediction of climate changes impact on species productivity and survival is of a special interest (O’Neill et al. 2008; Gömöry et al. 2012; Kapeller & Schüler 2012). Natural climate warming (shift towards south) or cooling (shift towards north) is simulated in provenance test when we use seeds from the parent stands from the north or to the south of a test plot. In new conditions, wide range of genetic variations of a species demonstrating its genetic differentiation and environmental sustainability can be observed (Petrov 1987). In the opinion of I. I. Kamalova (Nakvasina et al. 2008), it can take place because of genotype frequency shift from homeostasis in the areas of parent stands growing.

To study different adaptation of tree provenances to climate changes various parameters are used. For spruce provenances, height of trees of different ages (Beaulieu

*Corresponding author. Elena Nakvasina, e-mail: nakvasina@yandex.ru, phone: +7 818 221 6174
& Rainville 2005; Gömöry et al. 2012; Kapeller et al. 2012) or diameter growth (Suvanto et al., 2016) were used. We carried out the similar studies on Scots pine and spruce provenances response to climate change in terms of growth rate and seeds production (Nakvasina 2003, 2014; Nakvasina et al. 2008, 2016).

Study of intraspecific variability and phenotypic plasticity related to population origin and growing conditions is considered of higher priority (Mátys 2006; Garzón et al. 2011; Kapeller et al. 2012; Suvanto 2016).

In wide sense, plasticity means biological ability of species to adapt to environmental conditions. Phenotypic plasticity means ability of an organism to change its phenotype in response to changes in the environment without genetic change (Giennap et al. 2008; Price et al. 2003). Plasticity is based on homeostatic responses. Phenotypic plasticity provides stability of large populations, such as spruce populations (Gomez-Mestre & Jovani 2013).

However, species tests beyond its natural distribution area is of specific interest (Kapeller & Schüler 2012), as species response to climate changes can be explained by species distribution history, its migration from the distribution area center (Kapeller et al. 2012). For P. abies such opportunity is provided by provenance tests established in Russia. The eastern boundary of this species distribution area goes just within the Russian Plain area. Here, the species comes in contact with P. obovata and forms an introgressive hybridization zone.

We studied provenances of Picea abies (L.) Karst. and P. obovata (Ledeb.) in provenance trials located in the European North of Russia within the natural distribution area of P. obovata. Picea abies provenances grow in provenance trials beyond the distribution area of this species. Environmental conditions of the taiga zone considerably differ from optimal growing conditions for this species in the distribution area and therefore, it would make it possible to assess its phenotypic plasticity in extreme growth conditions. We can also compare phenotypic plasticity of P. abies and P. obovata. Provenances of P. obovata are tested in optimal growing conditions for this species or in simulated climate warming conditions.

2. Materials and methods

In the European North of Russia spruce provenances were tested in three test plots (Fig. 1) located in the southern taiga subzone (the Vologda Region, “Vologda” test plot, and in the middle taiga subzone (the Arkhangelsk Region, “Plesetsk” test plot, Komi Republic, “Komi” test plot). These plots make a part of the State Provenance Trial Network of the USSR established in 1970s (Rodin & Prokazin 1996, 1997; Shutyaev 1990). Geographical and environmental characteristics of the test plots are given in Table 1. Latitude difference of the test plots is 2.5–3.5° N, longitude difference is up to 14° E. In the Arkhangelsk and Vologda Regions climate is continental, in Komi Republic climate is strong continental result from proximity of the Urals. Provenances are grown on podsolic soils in spruce-blueberry shrub forest type.

Provenance trials were established in 1977. For tree planting 3-year seedlings were used for planting. Plant spacing: 0.75 m, row spacing: 2.5 m. Average block area – 0.25 ha, number of planted trees is about 400 in 3–6 replications. Supervisor of the test plots (Northern Research Institute of Forestry, Arkhangelsk, Russia) carries on regular observations.

For study of spruce provenances, the generally accepted Russian method of provenance tests of the main forest-forming species (Prokazin 1972) approved by the Basic Research Council on Forest Genetics, Selection, and Seed Production was used. For each provenance diameter (DBH) was measured at least for 100 randomly selected plants with accuracy of 0.1 cm. Average tree height for the provenance was determined using a height profile developed based on diameter and height values measured for at least 25 plants of different diameter classes in each variant. Survival was determined (in per cent) by number of survived trees against total number of trees initially planted out in blocks.

In our research 22 spruce provenances growing in each test plot were chosen. Geographical coordinates and forest types of their parent stands and taxation param-
eters of tested provenances are given in Table 2. List of tested provenances includes provenances from the northern, middle, and southern taiga subzones and mixed forest zone located within the Russian Plain (Fig. 1). Seven from 22 provenances are represented by *P. obovata* (L.) Karst., and six are represented by *P. abies* (Ledebr.). The rest provenances are represented by their introgressive hybrid forms distinguished by scale edges of mature macrostrobiles (Pravdin 1975; Orlova & Egorov 2010). Provenances represented by hybrid forms are of two types: hybrids with *P. obovata* characters (4 provenances) and hybrids with *P. abies* characters (6 provenances).

For ecological plasticity calculation the method developed by S. Eberhart and W. Russell (1966) in S. A. Petrov (1984) interpretation was used. The method is used in system experiments when the same provenances (at least three) are cultivated in different environmental conditions. The method by S. Eberhart and W. Russell (1966) is widely used in Russia and other countries for assessment of agricultural field and fruit sorts and species crop capacity (Scapin et al. 2000; Besedina et al. 2014; Gulyayashkin et al. 2014; Krasnova et al. 2014). This method was used in provenance trials for forest species plasticity assessment (Shutyev & Giertych 1997, 2000; Nakvasina et al. 2008).

According to the method (Eberhart & Russell 1966), total variability (plasticity) of a provenance under test conditions is characterized by linear regression coefficient ($b_i$). Provenances with $b_i > 1$ are characterized by high plasticity and easily adapt to cultivation conditions; in case of cultivation conditions improvement better results can be expected. Provenances with $b_i < 1$ have low

phenotypic plasticity and weak response to environmental conditions change; on cultivation conditions improvement better results are not expected. At the same time, in case of condition decline, results would not downgrade considerably. Provenances with \( b_i = 0 \) are in intermediate position (with average plasticity). This makes it possible to assess spruce provenances both in terms of their use for forest cultivation and in terms of their adaptation to climate changes.

The method makes it possible to calculate environmental condition index intended for assessment of differentiation of provenance cultivation conditions (Eberhart & Russell 1966; Petrov 1984).

The present study is based mainly on Eberhart and Russell (1966) model. Wricke’s ecovalence (1962) evaluate genotype stability and complements the Eberhart and Russell (1966) regression analysis. According to Kang et al. (1987) Wricke’s ecovalence is equivalent to Shukla (1967) and Russell (1966) regression analysis. A high value of Wricke’s ecovalence (\( W_i^2 \)) is considered as an indicator of low stability, while \( W_i^2 = 0 \) gives the most stability. The regression coefficient of Eberhart and Russell (\( b_i \)) and the Wricke’s ecovalence (\( W_i^2 \)) were calculated for each genotype and compared by correlation analysis.

Phenotypic plasticity was estimated based on three parameters: survival, diameter, height. For estimation of growth parameters of phenotypic plasticity we used average increment calculated as height and diameter divided by biological age of a spruce because the differences in years of observations and stands ages.

ANOVA (SPSS v 22.0, GLM procedure) with groups of plasticity and spruce species on survival and growth parameters of spruce provenances as fixed factors was used to test differences in survival and growth parameters, and interactions between them. For the statistical data analysis, correlation analysis was used. Significant value was accepted at the \( P < 0.05 \) level.

### 3. Results

Differences in growth conditions in the spruce test plots in the taiga zone of the Russian Plain are proved by environmental condition indices determined using the S. Eberhart & W. Russell (1966) method (Table 3). The best conditions when the index has positive value, the worst conditions when the index has negative value (Korzun & Bruilo 2011). In the test plots Plesetsk and Vologda environmental conditions of spruce growth are quite favorable; in the test plot Komi growth conditions are worse. Environmental conditions impact spruce provenance survival rather than diameter and height of survived trees.

Survival and growth rate of 22 spruce provenances in different test plots differ but have common behavior related to spruce age. Spruce provenances from low-latitudes (\( P. abies \)) have worse survival during first years after planting out. In this period northern provenances represented by \( P. obovata \) have better resistance to environmental conditions (Nakvasina et al. 1990; Tarkhanov 1998). They maintain better survival also later. In most cases, survived \( P. abies \) trees have higher growth rate than \( P. obovata \) (Nakvasina & Gvozdzhkina 2005; Fai zulin et al. 2011; Demina et al. 2013).

Table 4 shows the parameters of the phenotypic plasticity of the origin of spruce: Eberhart and Russell’s \( b_i \) and Wricke’s \( W_i^2 \). Provenances of plastic and non-plastic groups (\( b_i > 1 \) and \( b_i < 1 \)) by growth and survival occur among \( P. obovata, P. abies \) and their hybrid forms. Grouping of provenances by plasticity does not agree in some parameters. Plasticity grouping by survival and growth is the most similar in two biometrical indices (DBH and height), correlation ratio \( r \) is 0.7258 (significant at \( P = 0.05 \)). Wricke’s ecovalence (\( W_i^2 \)) is an indicator of genotype stability. A high value shows the most stable, while \( W_i^2 = 0 \) gives the greatest stability. In our experiment, \( W_i^2 \) had the more variations in survival (from 2.68 to 456.49) and lower in DBH and height (0.09 – 4.98 and 0.32 and 6.96). This is close to variability of Eberhart and Russell’s liner regression parameter \( b_i \).

Correlation coefficients (Table 5) were important for estimating mean values of and Eberhart and Russell’s coefficient (\( b_i \)) and Wricke’s ecovalence (\( W_i^2 \)), as well as pair combinations between them. The correlation between the coefficients was significant for survival (0.417). The same indicator has a significant correlation between mean values and Eberhart and Russell’s coefficient (\( b_i \)). Correlations between other pairs of combinations were not significant. It can be assumed that with a larger number of tested genotypes this effect can be stronger (Becker 1981).

### 4. Discussion

For practical purposes it is important to select genotypes that will respond to a changed environment and give the best results. Such a possibility is provided by the approach of Eberhart and Russell (1966), which proposes to evaluate the plasticity by the coefficient \( b_i \). Therefore, according to the linear regression indicator, the tested genotypes were divided into two groups: Group 1 – (\( b_i > 1 \)) – plastic populations; Group 2 – (\( b_i < 1 \)) – non-plastic.

Among \( P. obovata \) and its hybrid forms, the most provenances are assigned by survival and growth to Group 2 (\( b_i < 1 \)), i.e. non-plastic. It is especially typical
for survival. Provenance No 23 (P. obovata, Arkhangelsk Region, Kholmogory District) from the Northern taiga subzone is different as can be assigned to Group 1 by three indices. Three more provenances have high plasticity index (bi > 1) for certain parameters: for survival (P. obovata, Sverdlovsk Region, No 40) and for height (P. obovata, Perm Region, No 39 and hybrid form with properties of Picea obovata, Udmurtia, No 35).

For P. abies and its hybrid forms the high index (bi > 1) is observed more often and represents high plasticity of the species. It is especially typical for survival. Five provenances of P. abies and its hybrid forms characterize by high plasticity both in survival and growth. These are provenances from Leningrad (No 5), Pskov (No 7), Vologda (No 24), Kostroma (No 27) Regions, Karelia Republic (No 3). They are located in different zones and taiga subzones: in the middle and southern taiga subzones and mix forest zone. However, the area of initial stand habitats of these provenances is quite local and is restricted by 56º30´ – 61º40´ N and 30º30´ – 42º30´ E.

The genotype survival has a clear differentiation (P < 0.05) by selected groups of plasticity and by species and forms of spruce (Table 6). The stability of the provenances in the new environmental conditions during the testing of spruces genotypes can be considered as priority in the practical genotypes assessment. Growth (height and diameter) is less impacted by the environment. The provenances maintain hereditarily fixed growth parameters and implement them when the growing conditions change in accordance with the reaction norm.

Plastic provenances of Picea abies and its hybrid forms are concentrated near the western boundaries of the Russian Plain (Fig. 2). It can be a result of closeness of the spruce refugium located in the territory of Belovezhskaya Pushcha from where spruce migration towards north-east has occurred (Dering & Levandovski 2007). At the same time, plastic provenances of Picea obovata and its hybrid forms are dispersed all over the north-western part of the Russian Plain that can be a result from P. obovata propagation to the Russian Plain from Siberia via the Polar Urals (Popov 2005). In the North-Eastern part of the Russian Plain plastic spruce provenances mixed with provenances close to plastic ones, i.e. they are not plastic in all studied parameters (they can be named as partly plastic). Such genomic clustering of parent populations is typical of Eurasian spruce species (Melnikova et al. 2012).
According to Garzón et al. (2011), different response to climatic changes can be expected for species and provenances with different phenotypic plasticity. In general, *Picea abies*, due to its better plasticity, would be more responsive to climatic changes in production properties (survival and growth). *Picea obovata* is a more conservative species and would poorly respond to climatic changes. It agrees with a general conclusion made by Kapeller et al. (2012) for *Picea abies*, that southern spruce species from a zone with higher temperatures and less precipitation would be more suitable for use in new environmental conditions.

Gömöry et al. (2012) noted that high-latitude spruce provenances are more resistant and low-latitude spruce provenances are more sensitive to climate change. Persson (1998) considers it as a result of decrease of required cold resistance under climate warming.

In this case, in future, with climate warming in the Northern areas of the Russian Plain, we can expect further *Picea abies* dispersion and its suppression on *Picea obovata*. For species adaptation to climate warming several species generations will required (Beaulieu et al. 2005). It should be taken into consideration that forest ecosystems have high tolerance providing their high resistance to unfavorable environmental impact. In addition, so called adaptive delay (for about 100 years) of species response to climate changes takes place (Savolainen et al. 2004). Therefore, *P. abies* dispersion over the Russian Plain would be slow and first it would cause extension of introgressive hybridization zone. It can cause decrease of *P. abies* phenotypic plasticity due to hybridization with less plastic *P. obovata*.

5. Conclusions

*Picea abies* (L.) Karst. provenances have better phenotypic plasticity, including the response to the climate changes. In future, on sustainable climate warming, this species could predominate in the Russian Plain and start to force out *P. obovata* (Ledeb.).

Variability of phenotypic plasticity observed for populations of spruce species (*Picea abies* (L.) Karst. and *P. obovata* [Ledeb.]) and for their hybrids forms occurring in the contact zone proves necessity in further study of certain provenances. Selection based on provenances phenotypic plasticity would make it possible to solve some production problems related to adaptation of forest-forming species to climate changes.

Abstract

In time of climate change, close-to-nature silviculture is growing in importance as a tool for future forest management. The paper study the tree layer and natural regeneration of monospecific Norway spruce (Picea abies [L.] Karst.), trough mixed spruce-beech to dominant European beech (Fagus sylvatica L.) forests in Jizerské hory Mts., the Czech Republic. In the locality, shelterwood and selection system have been applied since 2000. The research objectives were to evaluate production parameters, structural diversity, species richness, natural regeneration dynamics and radial growth of individual tree species in relation to climatic factors and air pollution. The stand volume on permanent research plots amounted to 441 – 731 m$^3$ ha$^{-1}$ in initial stage of transformation. Natural regeneration showed high expansion of beech and decrease of spruce compared to mature tree species composition. Radial growth of spruce was in significant negative correlation with SO2 and NOx concentrations compared to no effect on beech increment. Moreover, spruce was more sensitive to significant years with extreme low radial growth. Beech was more stable in radial growth. Spruce was more resistant to air pollution and climatic stress in mixed stands. Low temperature was limiting factor of radial growth together with climate extremes (such as strong frosts and more frequent droughts) and biotic factors (bark beetle, beech scale). Close-to-nature management supporting admixed tree species should lead in future to diversification of stand structure toward higher species, spatial and age structure to mitigate negative effect of climatic change.

Key words: natural regeneration; forest transformation; stand structure; forest dynamics; air pollution; Czech Republic

1. Introduction

Pure and mixed forest stands of European beech (Fagus sylvatica L.) were the most widespread forests in the Middle Age in Europe (Packham et al. 2012). In the course of centuries intensive forest management has changed their original species composition and stand structure in many localities (von Oheimb 2005; Petritan et al. 2015). For example in the Czech Republic, beech was represented by 40.2% in natural forests, currently it is represented by 8.4% (MZe 2018). Forests of the temperate zone have usually undergone greater changes than other forest ecosystems (Terek & Dobrovic 2013). In Central Europe, natural forest ecosystems were mostly affected and constrained by unfavourable anthropogenic factors (Jantsch et al. 2013; Bošča et al. 2016) as a result of dense human population (Barna & Bosela 2015). In Central Europe, due to anthropic impacts, spruce monocultures take up a large portion of forest land (Spiecker et al. 2004). These stands have been repeatedly affected by disturbances in the last decades (Hlášny & Sitková 2010; Briner et al. 2013) and consequently their long-term sustainability is questioned (Grodzki 2010).

Currently, crucial factors influencing forest ecosystems in Central Europe are climate extremes (winter desiccation, summer drought, wind storm), pollutants (SO2, NOx, O3), bark beetle disturbances, excessive damage by ungulates (browsing, bark stripping) or inappropriate management (Flechard et al. 2011; Krejčí et al. 2013; Vacek et al. 2017a; Putalová et al. 2019). As in the last

*Corresponding author. Zdeněk Vacek, e-mail: vacekz@fld.czu.cz
years gradual changes have occurred in forest management approaches in Central Europe, there has been a shift from the preference of coniferous monocultures to the support of mixed stands, natural regeneration and broad-leaved species in general (Petritan et al. 2009; Slanař et al. 2017). Close-to-nature and sustainable forestry management practices have been increasingly applied (FAO 2006; Barbati et al. 2014). These alternative management strategies usually avoid a clear-cutting system while small-scale management and creation of mixed and structurally diversified forest stands is preferred (Schütz 1999; Tesaf et al. 2004; Puettmann et al. 2015). Increasing the proportion of deciduous tree species and optimizing age and spatial composition of forest stands follows these management objectives and is therefore one of the key objectives of the modern forestry (Schütz 2002; Bilek et al. 2011; Puettmann et al. 2015). Target trees should be composed of at least 30% share of the original tree species composition and its close-to-nature structure differentiation is recommended (Poleno et al. 2009). This trend is also a result of recent conferences on forest conservation in Europe (MCPFE 2015) and at the same time it has become a dominant forestry paradigm in many countries (Butler & Koontz 2005). The application of these modern principles should lead to an increase in stand resistance to disturbances and to an improvement in the ability of individual trees to survive (Jönsson et al. 2012; Neuner et al. 2014; Vacek et al. 2015). This is particularly important in areas with increasing extent of forest disturbances (Hlášny et al. 2017). Taking into account this trend, foresters try to reduce a difference in structural variability between natural and commercial forests and to establish a balance between ecological and socioeconomic functions of forest (Cardinall et al. 2004; Urlt et al. 2017). In this context Vacek et al. (2014b) and Remess et al. (2015) state that the stands that would undergo the process of transformation toward close-to-nature forests would fulfill ecological, environmental and socioeconomic functions of forest in a substantially better way.

European beech as one of the most important broad-leaved species in Europe (Packham et al. 2012; Chianucci et al. 2016) plays a crucial role in this trend of sustainable forest management (Bolte et al. 2007; Barna & Bosela 2015). It is very important from both economic (Shahverdi et al. 2013) and ecological aspects (Drobyshev et al. 2014). In Central Europe, beech represents a potentially dominant species of natural vegetation in humid to moderately dry areas of submontane zones under current climatic conditions (Ellenberg 1996). Nevertheless, the expected climate changes (Lorz et al. 2010; Bilela et al. 2012; Machar et al. 2017) can worsen its vitality and competitiveness (Fotelli et al. 2003). The expected regional warming and the related decreasing water availability are considered as a significant negative factor with an impact on vitality and productivity of forest ecosystems in Central Europe (IPCC 2007). On the other hand, beech is a relatively resistant tree species, especially at the centre of its distribution range, with regard to global climate change (Bolte et al. 2010; Bošel et al. 2016; Králiček et al. 2017). Králiček et al. (2017) or Kolář et al. (2017) concluded that European beech show higher stability and resistance in relation to climate changes (especially to droughts) compared to Norway spruce. Nevertheless, Gessler et al. (2007) showed also potential risks for this tree species in relation to climate change. Close-to-nature management strategies should solve both ecological risks and related economic risks (Seidl et al. 2014; Schelhaas et al. 2015).

The purpose of present paper is to assess the possibilities of stabilization of spruce monocultures in the process of their transformation by gradual increase of beech and structural differentiation of the forest stands in Jizerské hory Mts. For the research, mixed (spruce-beech) forest stands were selected with different proportions of beech at the initial stage of the transformation, focusing on the area where the beech is the only one prospective ameliorating and stabilising tree species in relation to ungulate browsing and climatic change. The study evaluates the structure and dynamics of spruce-beech forest stands in the 40-year transformation phase toward close-to-nature structure with emphasis on production, ecological stability and biodiversity under ongoing global climate change.

The main objectives were:

- to define production parameters, structure and biodiversity (vertical, horizontal, species and complex) of forest stands at the initial stage of forest transformation including dead wood characteristics,
- to quantify dynamics of diameter increment and resistance of European beech and Norway spruce on air pollution (SO₂, NOₓ, O₃), climatic factors (temperature, precipitation) and climate change,
- to estimate relationship among radial growth, tree species composition, climate and air pollution load in relation to forest stability,
- to quantify changes in structural diversity and species composition of natural regeneration compared to mature stand and the role of game damage in the process of transformation.

2. Materials and methods

2.1. Study area

The research was conducted on four permanent research plots (PRP) in the Jedlový důl area in the Protected Landscape Area Jizerské hory Mts. and Bird Conservation Area CZ0511008 Jizerské hory Mts., northern part of the Czech Republic (Fig. 1). The bedrock is composed of porphyritic medium-grained granite and granodiorite. Prevailing soil is Cambisols and Cryptopodzols (Vacek et al. 2003).

The mean annual temperature was around 3.8 °C and the mean annual sum of precipitation reached 1 220 mm with minimum temperature in January (−5.0 °C), resp. precipitation in April (73 mm) and maximum in July (13.1 °C, 144 mm) in 1960–2016 (Fig. 1). During this period, the sum of precipitation average decreased by 77 mm and temperature increased by 1.8 °C under climate change. On all PRP the growing season lasts for about 131 days, average temperature in the growing season was around 10.7 °C with sum of precipitation 646 mm. The study territory belongs to humid continental climate characterised by hot and humid summers and cold to severely cold winters (classification symbol Dfb) according to Köppen climate classification (Köppen 1936).

From the aspect of environmental pollution, SO₂ concentrations had increased since 1970s in connection with the operation of large coal firing power station Turów in Poland (Vacek et al. 2003). The quantity of emissions increased there more than ten times in the course of two decades (45,000 tons of SO₂ in 1957, 500,000 tons of SO₂ in 1980) – (Jirgle et al. 1983). Currently, a substantial decrease in SO₂ concentrations from 28 to 3 µg m⁻³ was reached since 1972. Average concentrations of NOₓ are around 7 µg m⁻³ and the O₃ exposure index AOT40F is 27,000 ppb h⁻¹.

The studied territory is covered by spruce-beech forests with individual admixture of sycamore maple (Acer pseudoplatanus L.), silver fir (Abies alba Mill.), rowan (Sorbus aucuparia L.) and silver birch (Betula pendula Roth; Table 1). Silver fir was introduced into these stands in the 80s and 90s of the 20th century through group underplantings. At the end of the 1970s and during the 1980s in connection with the air pollution load, gradual release of suppressed beechn trees started in declining spruce forest stands. Substantial care for the mature beech crowns contributed to their future fertility and natural regeneration. These silviculture practises have begun the initial transformation of spruce stands in study area of the Jizerské hory Mts. (Vacek & Cipra 1979). On PRP forest transformation based on the principles of shelterwood and selection system has been applied since 2000. In terms of phytocoenology PRP belong to acidophilous beech forests (the association Luzulo-luzuloidis-Fagetum sylvaticae Meusel 1937, Calamagrostio villosae-Fagetum Mikyška 1972) and partly forms of herb-rich beech forests (the association Dentario enneaphylli-Fagetum Oberdorfer ex W. et A. Matuszkiewicz 1960).

Fig. 1. The localization of spruce-beech forest stands on permanent research plots I – IV in the Jizerské hory Mts. with climatic characteristics (1960–2016).
2.2. Data collection

FieldMap technology (IFER-Monitoring and Mapping Solutions Ltd.) was used to determine the structure of the tree layer, dead wood and natural regeneration in 2015–2016 on four PRP of 50 × 50 m in size. The position of all individuals of the tree layer with diameter at breast height (DBH) ≥ 4 cm and crown projections were localized, minimally at 4 directions perpendicular to each other. DBH of the tree layer were measured with a metal calliper (accuracy 1 mm) and tree heights and heights of live crown base were measured with a Vertex laser hysrometer (accuracy 0.1 m; Haglöf, Sweden).

In 15 dominant and co-dominant trees of each main tree species (spruce and beech) on each PRP (only spruce on PRP 3), increment sample cores at DBH (130 cm) perpendicular to the axis of the tree along the slope and against the slope were taken by the Pressler’s borer. Annual ring widths were measured with an Olympus binocular magnifier (accuracy 0.01 mm) on the LINTAB measuring table (Rinntech) and recorded by TSAPWIN (Registograph).

For naturally regenerated individuals with DBH < 4 cm and height ≥ 150 cm these characteristics were measured on the whole PRP; position, height, height of live crown base, crown width (with a height measuring pole to the 1 cm) and damage by ungulate (branch browsing, bark stripping). For standing and lying dead wood (diameter ≥ 7 cm, length ≥ 1 m) the position, tree species and volume according to the Harmon et al. (1986) method were determined.

2.3. Data analysis

Based on measured dendrometric data of tree layer, stand volume (Petráš & Pajtlič 1991), stocking (stand density index – SDI) and canopy density (crown closure and crown projection area) were computed. For natural regeneration and tree layer species diversity by the following indices were evaluated: species richness \( D \) (Margalef 1958), species heterogeneity \( H' \) (Shannon 1948) and species evenness \( E \) (Pielou 1975). Structural and total diversity was evaluated by Arten-profile index \( A \) (Pretzsch 2006), diameter \( T_M \), and height \( T_M_h \) differentiation index (Füldner 1995), index of non-randomness \( \alpha \) (Mountford 1961), aggregation index \( R \) (Clark & Evans 1954) and total diversity index \( B \) (Jaehne & Dohrenbusch 1997) using the software Sibyla (Fabrika & Durský 2005). Ten criteria were implemented in order to characterize forest status (Table 2).

Characteristics describing the horizontal structure of individuals within the plot were calculated using software PointPro 2.2 (Zahradník & Puš 2010). The test of significance of differences from values expected for the random layout of points was carried out by Monte Carlo simulations. Mean values of the \( L \)-function were estimated as means of \( L \)-functions calculated for 1999 randomly generated point structures. The spatial relations of natural regeneration and tree layer were evaluated by the cross-type pair correlation function \( G(r) \) using software R (R Project). Layout maps were created in the ArcGIS (Esri).

The annual rings series were individually cross-dated (error correction of missing rings) using statistical tests in the PAST application program (SCIENCE) and, subsequently, subjected to visual inspection by Yamaguchi (1991). If a missing annual ring was found, a ring of 0.01 mm was inserted in its place. Individual curves from a PRP were age detrended by the 100 years spline and used to create the average annual-ring series in the ARSTAN program (Laboratory of Tree-Ring Research). Negative significant pointer years were analyzed for each tree and subsequently for all PRP and tree species according to Schwein-Gruber et al. (1990). These pointer years were tested as an extremely narrow annual ring reaching less than 40% of the mean diameter increment of tree in 4 preceding years. It was proven if such a strong reduction in radial growth occurred in at least 20% of the trees on the plot. Average annual ring series of the PRP were correlated with climatic data (precipitation, temperatures 1961–2015 from Bedřichov station – 777 a.s.l.) and with air pollution data (SO2 1975–2015, NOX 1992–2012 and AOT40F 1996–2012 from Desná-Souš Station – 772 a.s.l.). Both stations are located in the Jizerské hory Mts. within an 8-km range of the PRP. DendroClim software (DedroLab) was used to model the diameter increment in relation to climatic characteristics.

Statistical analyses were processed in the Statistica 12 (StatSoft, Tulsa). Radial growth dataset with air pollution and climatic factors were tested by the Pearson correlation coefficient. Unconstrained principal component analysis (PCA) in Canoco 5 (Smilauer & Lepš 2014) was used to analyse relationships between growth of beech and spruce on PRP, climate factors and air pollution data in 1975–2015. Data were log-transformed, centred and standardized before the analysis.

3. Results

3.1. Production parameters and structure of tree layer

Tree density ranged from 272 to 416 trees ha⁻¹ (in European beech 40 – 212 trees ha⁻¹ and in Norway spruce 10 – 328 trees ha⁻¹) with SDI 0.51 – 0.74 (Table 3). The stand volume reached 441 – 731 m³ ha⁻¹, while beech accounted for 0 – 544 m³ ha⁻¹ and spruce for 166 – 442 m³ ha⁻¹. The highest stand volume (731 m³ ha⁻¹) was found out on PRP III, and the lowest on PRP I (441 m³ ha⁻¹). Spruce-beech stands had dominant representation of Norway spruce on PRP I, II and III (60.7 – 99.9%), only on PRP IV European beech was dominant tree species (76.8%). The basal area was in the range of 36.0 – 50.4 m² ha⁻¹ (in beech 0.1 – 34.9 m² ha⁻¹ and in spruce 13.0 – 35.9 m² ha⁻¹). Periodic annual increment of stands ranged from 5.0 to 7.0 m³ ha⁻¹ y⁻¹ and mean annual increment was 3.4 – 4.5 m³ ha⁻¹ y⁻¹. Canopy closure was 57.6 – 92.0% and crown projection area ranged between 0.86 and 2.52 (Table 3).

Spruce-beech stands on PRP were two or three-storied stands. The trees on PRP reached the mean DBH of 35.3 – 45.1 cm, in beech it was 6.0 – 45.8 cm and in spruce 37.3 – 50.2 cm. On PRP I, III and IV the occurrence of diameter classes 32 – 36 and 36 – 40 cm was the highest, only on PRP II the class >56 cm was prevailing (Fig. 2). On PRP I – III beech prevailed in the small classes while on PRP IV it was spruce. The tallest individuals of beech and spruce on PRP reached the height of 33 – 37 m and 38 – 43 m, respectively. The heights of live crown base were highly variable both in beech and spruce. In the

![Fig. 2. Histogram of diameter classes by main tree species in a mixed stands on permanent research plots in 2016.](image-url)
understorey it was mostly 1 – 3 m and in the overstorey 7 – 19 m.

The occurrence of dead wood ranged from 4.3 to 31.8 m³ ha⁻¹ (on average 16.4 m³ ha⁻¹). The volume of lying dead wood was 0.0 – 18.2 m³ ha⁻¹ and standing dead wood was in range 2.7 – 22.6 m³ ha⁻¹. Comparing total stand volume on PRP, volume of dead wood (lying DW 30.2%, standing DW 69.8%) formed 2.6% and stand volume of living trees 97.4%.

3.2. Biodiversity of tree layer

Vertical structure according to the Arten-profile index A was medium to highly diversified (0.395 – 0.725; Table 4). Diameter differentiation TMd was low to medium (0.238 – 0.375), such as height differentiation TMh (0.180 – 0.341). Species richness D was low (0.166 – 0.178). Species heterogeneity expressed by entropy H’ indicated minimum to low biodiversity (0.009 – 0.283). According to species evenness E, biodiversity on PRP I was low (0.030) while biodiversity on the other PRP was very high (0.844 – 0.944). Total diversity according B indicated even structure on PRP IV (5.909) and uneven structure on the other PRP (6.219 – 6.457).

Horizontal structure of the tree layer of mixed stands with dominant representation of European beech and Norway spruce was regular on all PRP (significantly according to R and CS indices; Table 4, Fig. 3). Conversely the mostly random pattern of tree layer individuals according to their distance (spacing) was indicated by Ripley’s L-function. Regular horizontal structure was observed on PRP at small spacing in distance from tree stem to 3 – 4 m.

Fig. 3. Horizontal structure of mixed stands on permanent research plots in 2016.
3.3. Radial growth of European beech and Norway spruce

Dynamics of Norway spruce showed very strong growth depression in 1979–1987 with pronounced minimum growth in 1980–1982 that was caused by an interaction of air pollutants (SO$_2$), climate stress and bark beetle feeding (Fig. 4). This trend was not observed on PRP 8 where spruce is only admixed tree species. In spruce, years 1980, 1981, 1982 and 2004 were observed as the negative pointer years with extreme low radial growth. Generally, the highest variability in ring-width index was observed on PRP I and II (SD ± 0.25) with the highest share of spruce, while the relatively balanced radial growth of spruce was observed on beech dominated PRP IV (SD ± 0.16).

Growth depressions of European beech on PRP II, III and IV was observed in 1979, 1980 and 1982 with pronounced minimum growth in 1980 that were caused by the synergism of air pollutants, climate extreme and strong incidence of beech scale (Cryptococcus fagi). In beech, years 1997 and 2012 were observed as the negative pointer years with extreme low radial growth (Fig. 4). Higher balance of radial growth was manifested in beech (SD ± 0.14) compared to spruce (SD ± 0.22). Average diameter increment of spruce on PRP I, II, III and IV in 1960–2015 was in positive correlation with temperatures in April of the preceding year and current year ($r = 0.26 – 0.22$). Besides, radial growth showed a positive correlation with rainfall in May of the preceding year ($r = 0.25$) and a negative correlation with precipitation in November of the preceding year ($r = -0.23$) and April of current year ($r = -0.23$; Fig. 5).

Average diameter increment of beech on PRP II, III and IV in 1960–2015 was in positive correlation with temperatures in July and August of the preceding year ($r = 0.33 – 0.22$) and in April of the current year ($r = 0.32$). In addition, radial growth showed a positive correlation with precipitation in May of the current year ($r = 0.23$) and a negative correlation with precipitation in July of the previous year ($r = -0.23$).
prevailing year ($r = -0.48$) and current year ($r = -0.26$; Fig. 5).

Interactions among radial growth of beech and spruce, climate factors and SO$_2$ concentrations are presented in an ordination diagram of PCA (Fig. 6). The first ordination axis explains 43.2% of data variability, the first two axes together explain 82.2% and the first four axes 97.4%. The x-axis illustrates the radial growth of spruce stands and the y-axis represents the radial growth of beech. SO$_2$ concentrations (average and maximum ones) were negatively correlated with spruce radial growth while there was no effect on growth of beech. Spruce increment was in positive correlation with temperature, especially with average annual temperature and temperature in June and July of the current year. Beech increment was negatively correlated with precipitation. Overall, the effect of temperature on diameter increment was more significant in comparison with very low influence of precipitation. In the period of the 80s and 90s of the 20th century the radial growth was affected especially by high SO$_2$ concentrations while in the second half of the studied period (after 2000) there was a closer correlation between growth and air temperature.

The radial growth increment of spruce showed a significantly negative correlation with the mean annual and maximum daily ($r = -0.53$, $-0.56$; $p < 0.001$) SO$_2$ concentrations (Table 5). Specifically, the highest negative effect of SO$_2$ concentrations was observed in July and February ($r = -0.58$, $-0.51$; $p < 0.001$). The lowest effect of SO$_2$ was observed on PRP IV with dominant beech ($r = -0.44$, $p < 0.01$). Mean annual NO$_X$ concentrations had also negative effect on spruce increment ($r = -0.43$; $p < 0.05$). Ozone exposure had no effect on diameter increment of spruce. Spruce was significantly positively influenced by annual temperature and temperature in the growing season ($r = 0.46$, 0.41; $p < 0.01$), while the lowest non-significant effect was observed again on PRP IV ($p > 0.05$).

Generally, beech showed higher resistance to air pollutants load and was less influenced by summary climatic variables. O$_3$, NO$_X$, and SO$_2$ concentrations had no significant effect on radial growth of beech, such as temperature and precipitation during the year and in the growing season (Table 5).

### 3.4. Structure and diversity of natural regeneration

The number of natural regeneration (height $\geq$ 1.5 m) on PRP ranged from 1,800 (PRP IV) to 13,356 (PRP II) recruits ha$^{-1}$ (Table 6). Beech on PRP accounted for 7 – 100%, spruce for 0 – 89%, silver fir 0 – 1% and silver

![Fig. 6. Ordination diagram of PCA showing relationships between climate data (Tem – mean temperature, Pre – sum of precipitation, Act – current year, Las – preceding year, Veg – growing season, NonVeg – non-growing season, I–III, VI–VII – months), SO$_2$ concentrations (mean – mean annual concentration, max – maximum concentration) and tree-ring width (Ring – mean tree-ring width) for beech and spruce on permanent research plots I, II, III and IV; codes □ indicate years 1977–2015.](image)
birch 0 – 4%. Comparing tree species composition of natural regeneration to tree layer, significant expanse of beech regeneration was observed on all PRP (increase up to 71%) to the detriment of spruce and occurrence of admixed tree species (silver fir, sycamore maple, silver birch, rowan).

Evaluating species diversity of natural regeneration, species richness $D$ was low on PRP I–III (0.105 – 0.229) and medium on PRP IV (0.398; Table 7). Entropy $H'$ index showed minimum species heterogeneity on PRP II and III (0.013 – 0.019) and medium diversity on PRP IV (0.373 – 0.443). Species evenness $E$ was minimum on PRP II and III (0.018 – 0.019) and medium on PRP I and IV (0.340 – 0.483) and high on PRP II and III (0.502 – 0.558). Comparing natural regeneration and tree layer, higher diversity in natural regeneration was in species richness (+45%) and height differentiation (+106%), while species evenness was higher (+212%) in tree layer due to low occurrence of tree species. The spatial pattern of natural regeneration was significantly aggregated on all plots (Table 7). The clumpy pattern of recruits according to their distance (spacing) was indicated by Ripley’s $L$-function. Higher aggregation of recruits was proved in beech compared to spruce.

The mean height of recruits from 1.5 m was comparable on all plots, showing a left-skewed distribution. Mean height of natural regeneration ranged from 199 to 228

---

Notes: $D$ – species richness index, $H'$ – species heterogeneity index (entropy), $E$ – species evenness index, $TM_{h}$ – height differentiation index, $\alpha$ – index of non-randomness, $K$ – aggregation index, CS – index of cluster size.

* statistically significant $(p<0.05)$ for horizontal structure (in all cases aggregation).

The mean height of recruits from 1.5 m was comparable on all plots, showing a left-skewed distribution. Mean height of natural regeneration ranged from 199 to 228
cm, for beech it was from 216 to 262 cm, in spruce 155 – 273, in fir 186 cm, sycamore maple 215 cm and rowan 170 cm. The growth pattern of heights reached by natural regeneration according to tree species was similar on all plots. On all PRP the most frequent was first height class (150 – 170 cm) except advanced natural regeneration on PRP II (Fig. 8).

Mean damage by browsing and bark stripping caused by red deer (Cervus elaphus L.) was low on natural regeneration on PRP (< 5%), especially in spruce (2%) and in beech (6%). However, the opposite situation was in admixed tree species, the browsing of the leading shoot in silver fir amounted to 68%, in rowan to 82% and growth of sycamore maple was completely eliminated by game (damage 100%).

In relation to mature stands, the spatial relationships between natural regeneration and tree layer expressed by the pair correlation function was as random at distances longer than 2 m, only on PRP I it was so from 5 m. At shorter distances the pattern was significantly regular on all PRP that it indicated a negative influence of the tree layer on natural regeneration (Fig. 9).

4. Discussion

In recent years, relatively few studies have been published in Central Europe that deal with close-to-nature silviculture and forest transformation according to the guidelines of shelterwood or selection management system (Schütz 2001; Sterba & Zingg 2001; Souček 2002; Švec et al. 2015). Stand transformations are very important for sustainable forestry and contribute indirectly to faster adaptation to the climate change (Schelhaas et al. 2015). Mixed and structurally diversified stands compared to monospecific stands with homogenous stand structure are more resistant to disturbances (Metz et al. 2016). Moreover, diversification of silvicultural measures should allow both achieving production targets and maintaining biological and ecological diversity (Bergeron et al. 1999).

In studied PRP in the initial stage of transformation, the stand volume ranged from 441 to 731 m³ ha⁻¹, while beech and spruce were dominant tree species. Similar stand volume was reported from mountain forest in Central Europe (von Oheimb et al. 2005; Bulušek et al. 2016; Králiček et al. 2017). On the other hand, significantly higher stand volume (up to 1,237 m³ ha⁻¹) was reported from Uholka Ukrainian beech virgin forest (Trotsiuk et al. 2012 ). The volume of dead wood on study plots reached on average 16 m³ ha⁻¹. E.g. Hobi et al. (2015) and Kuchel (2012) reported the average volume of dead wood 136 m³ ha⁻¹, resp. 169 m³ ha⁻¹.

Biodiversity as an important factor plays a key role in all ecosystem components (Pimm et al. 2014; Bilek et al. 2016; Schulze et al. 2016). The results documented the medium-to very strongly diversified vertical structure of investigated stands. Complex stand diversity showed a mostly uneven structure while species richness was low. Natural regeneration reached higher values instead of species heterogeneity. Among the particular plots, PRP I differed by the presence of beech only in small diameter classes due to initial stage of transformation of monospecific spruce forest stand, and low biodiversity unlike the other PRP. These results are generally consistent with Gao et al. (2014), who demonstrated that old stands with multi-layered structure usually have higher species diversity. Mölder et al. (2008) or Barbier et al. (2009) considered the effects of several factors like age, canopy density and species composition as biodiversity determinants. Bilek et al. (2016) stated that biodiversity is influenced by forest management while Heinrichs and Schmidt (2009) directly confirmed an increase in stand diversity after a tending treatment contrary to stands without management.

The horizontal structure of the tree layer in our study was moderately regular, especially at short distances. Random pattern of trees was evident at higher distances,
such a prevailing random pattern in spruce-beech forest in Orlické hory Mts. (Králíček et al. 2017). However, in some studies clumpy pattern was reported (von Oheimb et al. 2005), that is usually the result of extreme sites conditions or growth of natural regeneration in canopy gaps (Sefidlí et al. 2007; Bulušek et al. 2016). In our research aggregated horizontal structure of regeneration prevailed similar to studies of Ambrož et al. (2015) and Králíček et al. (2017).

Average tree-ring width on the studied PRP was nearly the same in spruce (1.4 – 1.6 mm) and in beech (1.3 – 1.6 mm). Radial increment of spruce and beech from 0.5 to 1.5 mm was similar in the Orlické hory Mts. (Králíček et al. 2017). Higher radial increment of spruce compared to beech in spruce-beech stands was reported in southern Sweden (Bolte et al. 2010). The dominant diameter increment of spruce has decreased in the last 50 years, but in beech it has been relatively balanced. The growth depression of spruce particularly from 1980 to 1982 was caused by the synergism of air pollutants (especially SO₂ concentrations), climate and bark beetle outbreaks. In fact, 1980 was the coldest year within the cold period 1960–2016 (2.3 °C, mean 3.8 °C) followed by the extreme dry year 1982 (795 mm, mean 1 220). There were strong attacks of bark beetles in 1992–1997 with subsequent high radial increment due to better light availability. In beech decrease of radial growth in 1997 and 2012 was the effect of damage to beech crowns by icing and wet snow in the winter seasons 1996/1997 and 2011/2012. In April 1997 mean temperature reached −0.3 °C (mean in 1960–2016 2.6 °C). In spring 2012 the assimilating organs were damaged by late frost and by the subsequent mass outbreak of gall midge (Mikiola fagi). These results were confirmed also by other authors (Alles 1994; Vacek et al. 2015a; Králíček et al. 2017). A decrease in the radial growth of spruce in 2004–2015 in comparison with the years 1999–2003 was a result of precipitation decrease and increased temperatures. Generally, spruce was more sensitive to negative pointer years with extreme low radial growth compared to beech. Radial growth of spruce was also in significant negative correlation with SO₂ and NOₓ concentrations (no effect in beech), such as in other studies (Hauck et al. 2012; Králíček et al. 2017; Putalová et al. 2019). Moreover, spruce was damaged by insect pests and fungal pathogens to a larger extent (Bolte et al. 2010; Maaten-Theunissen & Bouriaud 2012). The competitiveness of beech in relation to spruce is higher. In our study, spruce was more resistant to air pollution and climatic stress in mixed beech dominant stand on PRP IV compared to spruce monospecific PRP I. Similarly, both species showed higher increment and resistance in mixtures compared to monocultures in Germany (Pretzsch et al. 2014).

Natural regeneration as an important component of close-to-nature management (Štícha et al. 2010; Bílek et al. 2014; Vacek et al. 2017b) was evaluated on all PRP. The number of recruits was in the range of 1,800 – 13,400 recruits ha⁻¹, that it is as higher density compared to spruce-beech forest in Orlické hory Mts. (Vacek et al. 2014b) or in north-eastern Germany (von Oheimb et al. 2005). The abundance of natural regeneration is mainly influenced by the quantity of seeds from the seed bank, successful germination and subsequent survival and growth of seedlings (Sagnard et al. 2007; Wagner et al. 2010). However, many factors are essential for subsequent survival and growth of natural regeneration in forest stands; among them, decreased stand canopy, sufficient light and favourable climatic conditions are the most important (Klopic & Boncina 2010; Vacek et al. 2015b). Natural regeneration of spruce has similar requirements when spruce requires more light than beech (Úradniček et al. 2009). It coincides with the negative influence of the tree layer on spatial pattern of natural regeneration confirmed by our study in at short distances lower than 2 to 5 m. Similar conclusions were drawn by Králíček et al. (2017) and Slanaf et al. (2017), but in extreme conditions the influence of tree layer may be positive (Vacek & Hejcman 2012; Bulušek et al. 2016).

In terms of tree species, natural regeneration shows significant increase of beech and decrease of spruce compared to mature tree species composition in study sites. Expansion of beech regeneration was also observed at higher altitudes (Dulamsuren et al. 2017; Vacek et al. 2017b). Not only changing climatic conditions, but also game pressure significantly influence tree species composition in natural regeneration. Game damage is one of the main factors driving species composition of naturally regenerated forests (Roth 1996; Weisberg & Bugmann 2003; Bernard et al. 2017). Although 90 – 120 ungulates are hunted in a study forestry section, regeneration of silver fir (68%), rowan (82 %) and especially sycamore maple (100 % damage) was heavily or completely eliminated by red deer. The contrary, the lowest browsing damage was caused to spruce (2%) and beech (6 %). Thus, in the study area, beech is the only one perspective deciduous tree species that is able to escape strong pressure of ungulates. Considerable silviculture care of the beech crowns has had a positive impact in terms of beech masting and natural regeneration. Unlike the beech, this type of management has not had a real impact on sycamore and fir due to decimation of natural regeneration by ungulates. The attractiveness of fir, rowan and sycamore for game was also confirmed in other part of Czechia (Vacek et al. 2014a, b, 2018), Slovakia (Konòpka & Pajtík 2015), Germany (Ammer 1996) and Italy (Motta 2003). The recommendation for limiting the game damage and protection of valuable admixed tree species is reduction of still increasing ungulate population, building of overwinter preserve, feeding of game in selected localities, reliable fencing of stands, establishing of fields for game or reintroduction of predators (Vrška et al. 2001; Konòpka et al. 2015; Cukor et al. 2017; Vacek 2017; Cukor et al. 2019).
5. Conclusions

Forest managers should make use of the possibilities of adaptation on climatic change with maximum involvement of natural processes. These modern silvicultural approaches should be directed at sustainable, ecologically and socio-economically acceptable forest development in the future. This study shows that beech is at altitudes of 640 – 810 m a.s.l. generally more resistant tree species than spruce. Spruce is more resistant to unfavourable environmental conditions (pollution and climatic extremes) in admixtures compared to monospecific stands. In terms of climate change, it is necessary to support resistance of forest to extreme climate events by increasing structural diversity and retaining species richness. It must be outlined that the studied forest stands are at the beginning of forest transformation with emphasis on production, ecological stability and biodiversity under ongoing global climate change. Based on our results the set silvicultural strategy leads despite the considerable pressure of ungulates to the formation of stable mixed forests able to mitigate climate change.
